Introduction

Among the several advances of the 20th century, nonlinear science is exceptional for its generality. Although the invention of radio was important for communications, the discovery of DNA structure for biology, the development of quantum theory for theoretical physics and chemistry, and the invention of the transistor for computer engineering, nonlinear science is significant in all these areas and many more. Indeed, it plays a key role in almost every branch of modern research, as this *Encyclopedia of Nonlinear Science* shows.

In simple terms, nonlinear science recognizes that the “whole is more than a sum of its parts,” providing a context for consideration of phenomena like tsunamis (tidal waves), biological evolution, atmospheric dynamics, and the electrochemical activity of a human brain, among many others. For a research scientist, nonlinear science offers novel phenomena, including the emergence of coherent structures (an optical soliton, e.g., or a nerve impulse) and chaos (characterized by the difficulties in making accurate predictions for surprisingly simple systems over extended periods of time). Both these phenomena can be studied using mathematical methods described in this *Encyclopedia*. From a more fundamental perspective, a wide spectrum of applications arises because nonlinear science introduces a paradigm shift in our collective attitude about causality. What is the nature of this shift?

Consider the difference between linear and nonlinear analyses. Linear analyses are characterized by the assumption that individual effects can be unambiguously traced back to particular causes. In other words, a compound cause is viewed as the linear (or algebraic) sum of a collection of simple causes, each of which can be uniquely linked to a particular effect. The total effect responding to the total cause is then considered to be just the linear sum of the constituent effects.

A fundamental tenet of nonlinear science is to reject this convenient, but often unwarranted,

assumption. Of course, the notion that components of complex causes can interact among themselves is not surprising to any thoughtful person who manages to get through an ordinary day of normal life, and it is not at all new. Twenty-four centuries ago, Aristotle described four types of cause (material, efficient, formal, and final), which overlap and intermingle in ways that were often overlooked in 20th-century thought but are now under scrutiny. Consider some examples of linear scientific thinking that are presently being reevaluated in the context of nonlinear science.

— Around the middle of the 20th century, behavioral psychologists adopted the theoretical position that human mental activity can be reduced to a sum of individual responses to specific stimuli that have been learned at earlier stages of development. Current research in neuroscience shows this perspective to be unwarranted.

— Some evolutionary psychologists believe that particular genes, located in the structure of DNA, can always be related in a one-to-one manner to individual features of an adult organism, leading to hunts for a “crime gene” that seem abhorrent to moralists. Nonlinear science suggests that the relation between genes and features of an adult organism is more intricate than the linear perspective assumes.

— The sad disintegration of space shuttle Columbia on the morning of February 1, 2003, set off a search for “the cause of the accident,” ignoring Aristotelian insights into the difficulties of defining such a concept, never mind sorting out the pieces. Did the mishap occur because the heat-resistant tiles were timeworn (a material cause)? Or because 1.67 pounds of debris hit the left wing at 775 ft/s during takeoff (an efficient cause)? Perhaps a management culture that discounted the importance of safety measures (a formal cause) should shoulder some of the blame.

— Cultural phenomena, in turn, are often viewed as the mere sum of individual psychologies,

ignoring the grim realities of war hysteria and lynch mobs, not to mention the "tulip craze" of 17th-century Holland, the more recent "dot-com bubble," and the outbreak of communal mourning over the death of Princess Diana.

Evolution of the Science

As the practice of nonlinear science involves such abstruse issues, one might expect its history to be checked, and indeed it is. Mathematical physics began with the 17th-century work of Isaac Newton, whose formulation of the laws of mechanical motion and gravitation explained how the Earth moves about the Sun, replacing a final cause (God's plan) with an efficient cause (the force of gravity). Because it assumed that the net gravitational force acting on any celestial body is the linear (vector) sum of individual forces, Newton's theory provides support for the linear perspective in science, as has often been emphasized. Nonetheless, the mathematical system Newton developed (calculus) is the natural language for nonlinear science, and he used this language to solve the two-body problem (collective motion of Earth and Moon)—the first nonlinear system to be mathematically studied. Also in the 17th century, Christiaan Huygens noted that two pendulum clocks (which he had recently invented) kept exactly the same time when hanging from a common support. (Confined to his room by an indisposition, Huygens observed the clocks over a period of several days, during which the swinging pendula remained in step.) If the clocks were separated to opposite sides of the room, one lost several seconds a day with respect to the other. From small vibrations transmitted through the common support, he concluded, the two clocks became synchronized—a typical nonlinear phenomenon.

In the 18th century, Leonhard Euler used Newton's laws of motion to derive nonlinear field equations for fluid flow, which were augmented a century later by Louis Navier and George Stokes to include the dissipative effects of viscosity that are present in real fluids. In their generality, these equations defied solution until the middle of the 20th century when, together with the digital computer, elaborations of the Navier-Stokes equations provided a basis for general models of the Earth's atmosphere and oceans, with implications for the vexing question of global warming. During the latter half of the 19th century, however, special analytic solutions were obtained by Joseph Boussinesq and related to experimental observations of hydrodynamic solitary waves by John Scott Russell. These studies—which involved a decade of careful observations of uniformly propagating "heaps of water" on canals and in wave tanks—were among the earliest research

programs in the area now recognized as nonlinear science. At about the same time, Pierre François Verhulst formulated and solved a nonlinear differential equation—sometimes called the logistic equation—to model the population growth of his native Belgium.

Toward the end of the 19th century, Henri Poincaré returned to Newton's original theme, presenting a solution of the three-body problem of celestial motion (e.g., a planet with two moons) in a mathematical competition sponsored by the King of Sweden. Interestingly, a serious error in this work was discovered prior to its publication, and he (Poincaré, not the Swedish king) eventually concluded that the three-body problem cannot be exactly solved. Now regarded by many as the birth of the "science of complexity," this negative result had implications that were not widely appreciated until the 1960s, when numerical studies of simplified atmospheric models by Edward Lorenz showed that nonlinear systems with as few as three degrees of freedom can readily exhibit the nonlinear phenomenon of chaos. (A key observation here was of an unanticipated sensitivity to initial conditions, popularly known as the "butterfly effect" from Lorenz's speculation that "the flap of a butterfly's wings in Brazil [might] set off a tornado in Texas.")

During the first half of the 20th century, the tempo of research picked up. Although still carried on as unrelated activities, there appeared a notable number of experimental and theoretical studies now recognized as precursors of modern nonlinear science. Among others, these include Albert Einstein's nonlinear theory of gravitation; nonlinear field theories of elementary particles (like the recently discovered electron) developed by Gustav Mie and Max Born; experimental observations of local modes in molecules by physical chemists (for which a nonlinear theory was developed by Reinhard Mecke in the 1930s, forgotten, and then redeveloped in the 1970s); biological models of predator-prey population dynamics formulated by Vito Volterra (to describe year-to-year variations in fish catches from the Adriatic Sea); observations of a profusion of localized nonlinear entities in solid-state physics (including ferromagnetic domain walls, crystal dislocations, polarons, and magnetic flux vortices in superconductors, among others); a definitive experimental and theoretical study of nerve impulse propagation on the giant axon of the squid by Alan Hodgkin and Andrew Huxley; Alan Turing's theory of pattern formation in the development of biological organisms; and Boris Belousov's observations of pattern formation in a chemical solution, which were at first ignored (under the mistaken assumption that they violated the second law of thermodynamics) and later confirmed and extended by Anatol

Zhabotinsky and Art Winfree. Just as the invention of the laser in the early 1960s led to numerous experimental and theoretical studies in the new field of nonlinear optics, the steady increases in computing power throughout the second half of the 20th century enabled ever more detailed numerical studies of hydrodynamic turbulence and chaos, whittling away at the long-established Navier–Stokes equations and confirming the importance of Poincaré's negative result on the three-body problem.

Thus, it was evident by 1970 that nonlinearity manifests itself in several remarkable properties of dynamical systems, including the following. (There are others, some no doubt waiting to be discovered.)

— Many nonlinear partial differential equations (wave equations, diffusion equations, and more complicated field equations) are often observed to exhibit localized or lump-like solutions, similar to Russell's hydrodynamic solitary wave. These "coherent structures" of energy or activity emerge from initial conditions as distinct dynamic entities, each having its own trajectory in space-time and characteristic ways of interacting with others. Thus, they are "things" in the normal sense of the word. Interestingly, it is sometimes possible to compute the velocity of emergent entities (their speeds and shapes) from initial conditions and express them as tabulated functions (theta functions or elliptic functions), thereby extending the analytic reach of nonlinear analysis. Examples of emergent entities include tornadoes, nerve impulses, magnetic domain walls, tsunamis, optical solitons, Jupiter's Great Red Spot, black holes, schools of fish, and cities, to name but a few. A related phenomenon, exemplified by meandering rivers, bolts of lightning, and woodland paths, is called filamentation, which also causes spotty output beams in poorly designed lasers.

— Surprisingly simple nonlinear systems (Poincaré's three-body problem is the classic example) are found to have chaotic solutions, which remain within a bounded region, while the difference between neighboring solution trajectories grows exponentially with time. Thus, the course of a solution trajectory is strongly sensitive to its initial conditions (the "butterfly effect"). Chaotic solutions arise in both energy-conserving (Hamiltonian) systems and dissipative systems, and they are fated to wander unpredictably as trajectories that cannot be accurately extended into the future for unlimited periods of time. As Lorenz pointed out, the chaotic behavior the Earth's atmosphere makes detailed meteorological predictions problematic, to the delight of the mathematician and the despair of the weatherman. Chaotic systems also exhibit "strange attractors" in the solution space, which are characterized by fractal (non-integer) dimensions.

— Nonlinear problems often display threshold phenomena, meaning that there is a relatively sharp boundary across which the qualitative nature of a solution changes abruptly. This is the basic property of an electric wall switch, the trigger of a pistol, and the flip-flop circuit that a computer engineer uses to store a bit of information. (Indeed, a computer can be viewed as a large, interconnected collection of threshold devices.) Sometimes called "tipping points" in the context of social phenomena, thresholds are an important part of our daily experience, where they complicate the relationship of causality to legal responsibility. Was it the last straw that broke the camel's back? Or did all of the straws contribute to some degree? Should each be blamed according to its weight? How does one assign culpability for the *Murder on the Orient Express*?

— Nonlinear systems with several spatial coordinates often exhibit spontaneous pattern formation, examples of which include fairy rings of mushrooms, oscillatory patterns of heart muscle activity under fibrillation (leading to sudden cardiac arrest), weather fronts, the growth of form in a biological embryo, and the Gulf Stream. Such patterns can be chaotic in time and regular in space, regular in time and chaotic in space, or chaotic in both space and in time, which in turn is a feature of hydrodynamic turbulence.

— If the input to (or stimulation of) a nonlinear system is a single frequency sinusoid, the output (or response) is nonsinusoidal, comprising a spectrum of sinusoidal frequencies. For lossless nonlinear systems, this can be an efficient means for producing energy at integer multiples of the driving frequency, through the process of harmonic generation. In electronics, this process is widely used for digital tuning of radio receivers. Taking advantage of the nonlinear properties of certain transparent crystals, harmonic generation is also employed in laser optics to create light beams of higher frequency, for example, conversion of red light to blue.

— Another nonlinear phenomenon is the synchronization of weakly coupled oscillators, first observed by the ailing Huygens in the winter of 1665. Now recognized in a variety of contexts, this effect crops up in the frequency locking of electric power generators tied to the same grid and the coupling of biological rhythms (circadian rhythms in humans, hibernation of bears, and the synchronized flashing of Indonesian fireflies), in addition to many applications in electronics. Some suggest that neuronal firings in the neocortex may be mutually synchronized.

— Shock waves are familiar to most of us as the boom of a jet airplane that has broken the sound barrier or the report of a cannon. Closely related

from a mathematical perspective are the bow wave of a speedboat, the breaking of onshore surf, and the sudden automobile pileups that can occur on a highway that is carrying traffic close to its maximum capacity.

— More complicated nonlinear systems can be hierarchical in nature. This comes about when the emergence of coherent states at one level provides a basis for new nonlinear dynamics at a higher level of description. Thus, in the course of biological evolution, chemical molecules emerged from interactions among the atomic elements, and biological molecules then emerged from simpler molecules to provide a basis for the dynamics of a living cell. From collections of cells, multicellular organisms emerged, and so on up the evolutionary ladder to creatures like ourselves, who comprise several distinct levels of biological dynamics. Similar structures are observed in the organization of coinage and of military units, not to mention the hierarchical arrangement of information in the human brain.

Often, qualitatively related behaviors—involving one or more of such nonlinear manifestations—are found in models that arise from different areas of application, suggesting the need for interdisciplinary communications. By the early 1970s, therefore, research in nonlinear science was in a state that the physical chemists might describe as “supersaturated.” Dozens of people across the globe were working on one facet or another of nonlinear science, often unaware of related studies in traditionally unrelated fields. During the mid-1970s, this activity experienced a “phase change,” which can be viewed as a collective nonlinear effect in the sociology of science. Unexpectedly, a number of conferences devoted entirely to nonlinear science were organized, with participants from a variety of professional backgrounds, nationalities, and research interests eagerly contributing. Solid-state physicists began to talk seriously with biologists, neuroscientists with chemical engineers, and meteorologists with psychologists. As interdisciplinary barriers crumbled, these unanticipated interactions led to the founding of centers for nonlinear science and the launching of several important research journals amid an explosion of research activity. By the early 1980s, nonlinear science had gained recognition as a key component of modern inquiry, playing a central role in a wide spectrum of activities. In the terminology introduced by Thomas Kuhn, a new paradigm had been established.

About this Book

The primary aim of this *Encyclopedia* is to provide a source from which undergraduate and graduate

students in the physical and biological sciences can study how concepts of nonlinear science are presently understood and applied. In addition, it is anticipated that teachers of science and research scientists who are unfamiliar with nonlinear concepts will use the work to expand their intellectual horizons and improve their lectures. Finally, it is hoped that this book will help members of the literate public—philosophers, social scientists, and physicians, for example—to appreciate the wealth of natural phenomena described by a science that does not discount the notion of complex causality.

An early step in writing the *Encyclopedia* was to choose the entry subjects—a difficult task that was accomplished through the efforts of a distinguished Board of Advisers (see page xiii), with members from Australia, Germany, Italy, Japan, Russia, the United Kingdom, and the United States. After much sifting and winnowing, an initial list of about a thousand suggestions was reduced to the 438 items given on pages 1–1010. Depending on the subject matter, the entries are of several types. Some are historical or descriptive, while others present concepts and ideas that require notations from physics, engineering, or mathematics. Although most of the entries were planned to be about a thousand words in length, some—covering subjects of greater generality or importance—are two or four times as long.

Of the many enjoyable aspects in editing this *Encyclopedia*, the most rewarding has been working with those who wrote it—the contributors. The willing way in which these busy people responded to entry invitations and their enthusiastic preparation of assignments underscores the degree to which nonlinear science has become a community with a healthy sense of professional responsibility. In every case, the contributors have tried to present their ideas as simply as possible, with a minimum of technical jargon. For a list of the contributors and their affiliations, see pages xv–xxxi from which it is evident that they come from about 30 different countries, emphasizing the international character of nonlinear science.

A proper presentation of the diverse professional perspectives that make up nonlinear science requires careful organization of the *Encyclopedia*, which we attempt to provide. Although each entry is self-contained, the links among them can be explored in several ways. First, the **Thematic List** on pages xxxix–xliii groups entries within several categories, providing a useful summary of related entries through which the reader can surf. Second, the entries have “**See also**” notes, both within the text and at the end of the entry, encouraging the reader to browse outwards from a starting node. Finally, the **Index** contains a detailed list of

topics that do not have their own entries but are discussed within the context of broader entries. If you cannot find an entry on a topic you expected to find, use the **Thematic List or Index** to locate the title of the entry that contains the item you seek. Additionally, all entries have selected bibliographies or suggestions for further reading, leading to original research and textbooks that augment the overview approach to which an encyclopedia is necessarily limited. Although much of nonlinear science evolved from applied mathematics, many of the entries contain no equations or mathematical symbols and can be absorbed by the general reader. Some entries are necessarily technical, but efforts have been made to explain all terms in simple English. Also, many entries have either line diagrams expanding on explanations given in the text or photographs illustrating typical examples. Typographical errors will be posted on the encyclopedia web site at <http://www.routledge-ny.com/ref/nonlinearsci/>.

The editing of this *Encyclopedia of Nonlinear Science* culminates a lifetime of study in the area, leaving me indebted to many. First is the Acquisitions Editor, Gillian Lindsey, who conceived of the project, organized it, and carried it from its beginnings

in London across the ocean to publication in New York. Without her dedication, quite simply, the *Encyclopedia* would not exist. Equally important to reaching the finished work were the efforts of the advisers, contributors, and referees, who, respectively, planned, wrote, and vetted the work, and to whom I am deeply grateful. On a broader time-span are colleagues and students from the University of Wisconsin, Los Alamos National Laboratory, the University of Arizona, and the Technical University of Denmark, with whom I have interacted over four decades. Although far too many to list, these collaborations are fondly remembered, and they provide the basis for much of my editorial judgment. Finally, I express my gratitude for the generous financial support of research in nonlinear science that has been provided to me since the early 1960s by the National Science Foundation (USA), the National Institutes of Health (USA), the Consiglio Nazionale delle Ricerche (Italy), the European Molecular Biology Organization, the Department of Energy (USA), the Technical Research Council (Denmark), the Natural Science Research Council (Denmark), the Thomas B. Thriges Foundation (Denmark), and the Fetzer Foundation (USA).

Maps
Quantum theory
Rössler systems

Gendelman, Oleg

*Faculty of Mechanical Engineering, Israel Institute of
Technology, Israel*
Heat conduction

Giuliani, Alessandro

*Environment and Health Department, Istituto Superiore
di Sanità, Rome, Italy*
Algorithmic complexity

Glass, Leon

*Isadore Rosenfeld Chair and Professor of Physiology,
McGill University, Canada*
Cardiac arrhythmias and the electrocardiogram

Glendinning, Paul

*Professor, Department of Mathematics, University of
Manchester Institute of Science and Technology, UK*
Hénon map
Invariant manifolds and sets
Routes to chaos

Goriely, Alain

*Professor, Department of Mathematics, University of
Arizona, USA*
Normal forms theory

Grand, Steve

Director, Cyberlife Research Ltd., Shipham, UK
Artificial life

Gratrix, Sam

*Maths Department, Imperial College of Science,
Technology and Medicine, UK*
Kuramoto–Sivashinsky equation

Grava, Tamara

*Mathematical Physics Sector, International school for
Advanced Studies, Trieste, Italy*
Hodograph transform
 N -soliton formulas
Zero-dispersion limits

Grimshaw, Roger

*Professor, Department of Mathematical Sciences,
Loughborough University, UK*
Group velocity
Korteweg–de Vries equation
Water waves

Haken, Hermann (Adviser)

*Professor Emeritus, Fakultät für Physik, University of
Stuttgart, Germany*
Gestalt phenomena
Synergetics

Halburd, Rodney G.

*Lecturer, Department of Mathematical Sciences,
Loughborough University, UK*
Einstein equations

Hallinan, Jennifer

*Institute for Molecular Bioscience, The University of
Queensland, Australia*
Game of life
Game theory

Hamilton, Mark

*Professor, Department of Mechanical Engineering,
University of Texas at Austin, USA*
Nonlinear acoustics

Hamm, Peter

*Professor, Physikalisch-Chemisches Institut, Universität
Zürich, Switzerland*
Franck–Condon factor
Hydrogen bond
Pump-probe measurements

Hasselblatt, Boris

*Professor, Department of Mathematics, Tufts University,
USA*
Anosov and Axiom-A systems
Measures
Phase space

Hastings, Alan

*Professor, Department of Environmental Science and
Policy, University of California, USA*
Epidemiology

Hawkins, Jane

*Professor, Department of Mathematics, University of
North Carolina at Chapel Hill, USA*
Ergodic theory

Helbing, Dirk

*Institute for Economics and Traffic, Dresden University
of Technology, Germany*
Traffic flow

Henry, Bruce

*Department of Applied Mathematics, University of New
South Wales, Australia*
Equipartition of energy
Hénon–Heiles system

Henry, Bryan

*Department of Chemistry and Biochemistry, University
of Guelph, Canada*
Local modes in molecules

Hensler, Gerhard

*Professor, Institut für Astronomie, Universitäts-
Sternwarte Wien, Austria*
Galaxies

Herrmann, Hans

*Institute for Computational Physics, University of
Stuttgart, Germany*
Dune formation

Hertz, John

*Professor, Nordic Institute for Theoretical Physics,
Denmark*
Attractor neural networks

Hietarinta, Jarmo

*Professor, Department of Physics, University of Turku,
Finland*
Hirota's method

Hill, Larry

*Technical Staff Member, Detonation Science &
Technology, Los Alamos National Laboratory, USA*
Evaporation wave

Hjorth, Poul G.

*Associate Professor, Department of Mathematics,
Technical University of Denmark, Denmark*
Kolmogorov–Arnol'd–Moser theorem

Holden, Arun

*Professor of Computational Biology, School of Biomedical
Sciences, University of Leeds, UK*
Excitability
Hodgkin–Huxley equations
Integrate and fire neuron
Markin–Chizmadzhev model
Periodic bursting
Spiral waves

Holstein-Rathlou, N.-H.

*Professor, Department of Medical Physiology,
University of Copenhagen, Denmark*
Nephron dynamics

Hommes, Cars

Professor, Center for Nonlinear Dynamics in Economics and Finance, Department of Quantitative Economics, University of Amsterdam, The Netherlands
Economic dynamics

Hone, Andrew

Lecturer in Applied Mathematics, Institute of Mathematics & Actuarial Science, University of Kent at Canterbury, UK
Extremum principles
Ordinary differential equations, nonlinear
Riccati equations

Hood, Alan

Professor, School of Mathematics and Statistics, University of St Andrews, UK
Characteristics

Houghton, Conor

Department of Pure and Applied Mathematics, Trinity College Dublin, Ireland
Instantons
Yang–Mills theory

Howard, James E.

Research Associate, Department of Physics, University of Colorado at Boulder, USA
Nontwist maps
Regular and chaotic dynamics in atomic physics

Ivey, Thomas A.

Department of Mathematics, College of Charleston, USA
Differential geometry
Framed space curves

Jiménez, Salvador

Professor, Departamento de Matemáticas, Universidad Alfonso X El Sabio, Madrid, Spain
Charge density waves
Dispersion relations

Joannopoulos, John D.

Professor, Department of Physics, Massachusetts Institute of Technology, USA
Photonic crystals

Johansson, Magnus

Department of Physics and Measurement Technology, Linköping University, Sweden
Discrete nonlinear Schrödinger equations

Johnson, Steven G.

Assistant Professor, Department of Mathematics, Massachusetts Institute of Technology, USA
Photonic crystals

Joshi, Nalini

Professor, School of Mathematics and Statistics, University of Sydney, Australia
Solitons

Kaneko, Kunihiko

Department of Pure and Applied Sciences, University of Tokyo, Japan
Coupled map lattice

Kantz, Holger

Professor of Theoretical Physics, Max Planck Institut für komplexer Systeme, Germany
Time series analysis

Kennedy, Michael Peter

Professor of Microelectronic Engineering, University College, Cork, Ireland
Chua's circuit

Kevrekidis, I.G.

Professor, Department of Chemical Engineering, Princeton University, USA
Wave of translation

Kevrekidis, Panayotis G.

Assistant Professor, Department of Mathematics and Statistics, University of Massachusetts, Amherst, USA
Binding energy
Collisions
Wave of translation

Khanin, Konstantin

Professor, Department of Mathematics, Heriot-Watt University, UK
Denjoy theory

Khovanov, Igor A.

Department of Physics, Saratov State University, Russia
Quasiperiodicity

Khovanova, Natalya A.

Department of Physics, Saratov State University, Russia
Quasiperiodicity

King, Aaron

Assistant Professor, Department of Ecology and Evolutionary Biology, University of Tennessee, Knoxville, USA
Phase plane

Kirby, Michael J.

Professor, Department of Mathematics, Colorado State University, USA
Nonlinear signal processing

Kirk, Edilbert

*Meteorologisches Institut, Universität
Hamburg, Germany*
General circulation models of the atmosphere

Kivshar, Yuri (Adviser)

*Nonlinear Physics Center, Australian National
University, Australia*
Optical fiber communications

Kiyono, Ken

*Research Fellow of the Japan Society for the Promotion of
Science, Educational Physiology Laboratory, University
of Tokyo, Japan*
Dripping faucet

Knott, Ron

Department of Mathematics, University of Surrey, UK
Fibonacci series

Kocarev, Liupco

*Associate Research Scientist, Institute for Nonlinear
Science, University of California, San Diego, USA*
Damped-driven anharmonic oscillator

Konopelchenko, Boris G.

*Professor, Dipartimento di Fisica, University of Lecce,
Italy*
Multidimensional solitons

Konotop, Vladimir V.

*Centro de Física Teórica e Computacional Complexo
Interdisciplinar da Universidade de Lisboa, Portugal*
Wave propagation in disordered media

Kosevich, Arnold

*B. Verkin Institute for Low Temperature Physics and
Engineering, National Academy of Sciences of Ukraine,
Kharkov, Ukraine*
Breathers
Dislocations in crystals
Effective mass
Landau–Lifshitz equation
Superfluidity
Superlattices

Kovalev, Alexander S.

*Institute for Low Temperature Physics and Engineering,
National Academy of Sciences of Ukraine, Ukraine*
Continuum approximations
Topological defects

Kramer, Peter R.

*Assistant Professor, Department of Mathematical
Sciences, Rensselaer Polytechnic Institute, USA*
Brownian motion
Fokker–Planck equation

Krinsky, Valentin

Professor, Institut Non-Lineaire de Nice, France
Cardiac muscle models

Kuramoto, Yoshiki (Adviser)

Department of Physics, Kyoto University, Japan
Phase dynamics

Kurin, V.

*Institute for Physics of Microstructures, Russian
Academy of Science, Russia*
Cherenkov radiation

Kuvshinov, Viatcheslav I.

*Professor, Institute of Physics, Belarus Academy of
Sciences, Belarus*
Black holes
Cosmological models
Fractals
General relativity

Kuzmin, Andrei

*Professor, Institute of Physics, Belarus Academy of
Sciences, Belarus*
Fractals

Kuznetsov, Vadim

*Advanced Research Fellow, Department of Applied
Mathematics, University of Leeds, UK*
Rotating rigid bodies

LaBute, Montiago X.

*Theoretical Biology and Biophysics Group,
Los Alamos National Laboratory, USA*
Protein structure

Lakshmanan, Muthusamy

*Professor, Department of Physics, Bharathidasan
University, Tiruchirapalli, India*
Equations, nonlinear
Nonlinear electronics
Spin systems

Landa, Polina S.

*Professor, Department of Physics, Moscow State
University, Russia*
Feedback
Pendulum
Quasilinear analysis
Relaxation oscillators

Landsberg, Peter

*Professor, Faculty of Mathematical Studies, University of
Southampton, UK*
Detailed balance

Lansner, Anders

Department of Numerical Analysis and Computer Science (NADA), Royal Institute of Technology (KTH), Sweden

Cell assemblies

Neural network models

Lee, John

Professor, Department of Mechanical Engineering, McGill University, Canada
Flame front

Lega, Joceline

Associate Professor, Department of Mathematics, University of Arizona, USA
Equilibrium
Fredholm theorem

Lepeshkin, Nick

The Institute of Optics, University of Rochester, USA
Frequency doubling

Levi, Decio

Professor, Dipartimento di Ingegneria Electronica, Università degli Studi Roma tre, Italy
Delay-differential equations

Lichtenberg, Allan J.

Professor, Department of Electrical Engineering and Computer Science, University of California at Berkeley, USA
Arnol'd diffusion
Averaging methods
Electron beam microwave devices
Fermi acceleration and Fermi map
Fermi–Pasta–Ulam oscillator chain
Particle accelerators
Phase-space diffusion and correlations

Liley, David

School of Biophysical Sciences and Electrical Engineering, Swinburne University of Technology, Australia
Electroencephalogram at mesoscopic scales

Lonngren, Karl E.

Professor, Department of Electrical and Computer Engineering, University of Iowa, USA
Plasma soliton experiments

Losert, Wolfgang

Assistant Professor, Department of Physics, IPST and IREAP, University of Maryland, USA
Granular materials
Pattern formation

Lotrič, Maja-Bračič

Faculty of Electrical Engineering, University of Ljubljana, Slovenia

Associate Professor, School of Mathematics and Statistics, University of Sydney, Australia
Jupiter's Great Red Spot

MacClune, Karen Lewis

Hydrologist, SS Papadopolus & Associates, Boulder, Colorado, USA
Glacial flow

Maggio, Gian Mario

ST Microelectronics and Center for Wireless Communications (CWC), University of California at San Diego, USA
Damped-driven anharmonic oscillator

Maini, Philip K.

Professor, Centre for Mathematical Biology, Mathematical Institute, University of Oxford, UK
Morphogenesis, biological

Mainzer, Klaus

Professor, Director of the Institute of Interdisciplinary Informatics, Department of Philosophy of Science, University of Augsburg, Germany
Artificial intelligence
Cellular nonlinear networks
Dynamical systems

Malomed, Boris A.

Professor, Department of Interdisciplinary Studies, Faculty of Engineering, Tel Aviv University, Israel

Complex Ginzburg–Landau equation
 Constants of motion and conservation laws
 Multisoliton perturbation theory
 Nonlinear Schrödinger equations
 Power balance

Manevitch, Leonid

Professor, Institute of Chemical Physics, Russia
 Heat conduction
 Mechanics of solids
 Peierls barrier

Manneville, Paul

Laboratoire d'Hydrodynamique (LadHyX), École Polytechnique, Palaiseau, France
 Spatiotemporal chaos

Marklof, Jens

School of Mathematics, University of Bristol, UK
 Cat map

Marsden, Jerrold E.

*Professor of Control and Dynamical Systems
 California Institute of Technology, Pasadena, USA*
 Berry's phase

Martínez, Pedro Jesús

Department of Theory and Simulation of Complex Systems, Instituto de Ciencia de Materiales de Aragon, Spain
 Frenkel–Kontorova model

Masmoudi, Nader

Associate Professor, Department of Mathematics, Courant Institute of Mathematical Sciences, New York University, USA
 Boundary layers
 Rayleigh–Taylor instability

Mason, Lionel

Mathematical Institute, Oxford University, UK
 Twistor theory

Mayer, Andreas

Institute for Theoretical Physics, University of Regensburg, Germany
 Surface waves

McKenna, Joe

Professor, Department of Mathematics, University of Connecticut, USA
 Tacoma Narrows Bridge collapse

McLaughlin, Kenneth

Associate Professor, Department of Mathematics, University of North Carolina at Chapel Hill, USA
 Random matrix theory III: Combinatorics

McLaughlin, Richard

Associate Professor, Department of Mathematics, University of North Carolina, Chapel Hill, USA
 Plume dynamics

McMahon, Ben

Theoretical Biology and Biophysics Group, Los Alamos National Laboratory, USA
 Protein dynamics
 Protein structure

Meiss, James

Professor, Department of Applied Mathematics, University of Colorado at Boulder, USA
 Hamiltonian systems
 Standard map
 Symplectic maps

Minkevich, Albert

Professor of Theoretical Physics, Belorussian State University, Minsk, Belarus
 Cosmological models
 General relativity

Miura, Robert

Professor, Department of Mathematical Sciences, New Jersey Institute of Technology, USA
 Nonlinear toys

Moloney, Jerome V.

Professor, Department of Mathematics, University of Arizona, USA
 Nonlinear optics

Moore, Richard O.

Assistant Professor, Department of Mathematical Sciences, New Jersey Institute of Technology, USA
 Harmonic generation

Mørk, Jesper

Professor, Optoelectronics, Research Center COM, Technical University of Denmark, Denmark
 Semiconductor laser

Mornev, Oleg

Senior Researcher, Institute of Theoretical and Experimental Biophysics, Russia
 Geometrical optics, nonlinear
 Gradient system
 Zeldovich–Frank–Kamenetsky equation

Mosekilde, E.

Professor, Department of Physics, Technical University of Denmark, Denmark
 Nephron dynamics

Mueller, Stefan C.

*Department of Biophysics, Otto-von-Guericke-
Universität Magdeburg, Germany*
Scroll waves

Mullin, Tom

*Professor of Physics and Director of Manchester Centre
for Nonlinear Dynamics, University of Manchester, UK*
Bifurcations
Catastrophe theory
Taylor–Couette flow

Mygind, Jesper

*Professor, Department of Physics, Technical University of
Denmark, Denmark*
Josephson junctions
Superconducting quantum interference device

Nakamura, Yoshiharu

*Associate Professor, Institute of Space and Astronautical
Science, Kanagawa, Japan*
Plasma soliton experiments

Natiello, Mario

*Centre for Mathematical Sciences, Lund University,
Sweden*
Lasers

ABLOWITZ-KAUP-NEWELL-SEGUR SYSTEM

In 1967, Gardner, Greene, Kruskal, and Miura (or GGKM) (Gardner et al., 1967) showed that the Korteweg-de Vries (KdV) equation

$$q_t + 6qq_x + q_{xxx} = 0, \quad (1)$$

with rapidly decaying initial data on $-\infty < x < \infty$, can be linearized using direct and inverse scattering methods associated with the linear Schrödinger equation

$$v_{xx} + [k^2 + q(x, t)]v = 0. \quad (2)$$

The KdV equation is of practical interest, having been first derived in the study of long water waves (Korteweg & de Vries, 1895) and subsequently in several other areas of applied science.

In the method proposed by Gardner et al., the solitary wave (soliton) solution to the KdV equation (1)

$$q = 2\kappa^2 \operatorname{sech}^2 \kappa(x - 4\kappa^2 t - x_0)$$

and multisoliton solutions are associated with the discrete spectrum of Equation (2). The discrete eigenvalues were shown to be invariants of the KdV motion; for example, the above soliton solution is associated with the discrete eigenvalue of Equation (2) at $k = i\kappa$.

At that time, it was not clear whether the method could be applied to other physically significant equations. In 1972, however, Zakharov and Shabat (1972) used an operator formalism developed by Lax (1968) to show that the nonlinear Schrödinger (NLS) equation

$$iq_t + q_{xx} + \sigma|q|^2 q = 0, \quad (3)$$

with rapidly decaying initial data on $-\infty < x < \infty$, could also be linearized by direct and inverse scattering methods.

The NLS equation was known to arise in many physical contexts (Benney & Newell, 1967) and in 1973 Hasegawa and Tappert showed that the NLS equation describes the long-distance dynamics of nonlinear pulses in optical fibers (Hasegawa & Tappert, 1973). Motivated by these developments and indications that other equations fit into this category, David Kaup, Alan Newell, Harvey Segur, and the present author (Ablowitz et al., 1973, 1974) studied the following modification of the Zakharov-Shabat system:

$$\begin{aligned} v_{1x} &= -i\zeta v_1 + qv_2, \\ v_{2x} &= i\zeta v_2 + rv_1, \end{aligned} \quad (4)$$

$$\begin{aligned} v_{1t} &= Av_1 + Bv_2, \\ v_{2t} &= Cv_1 + Dv_2. \end{aligned} \quad (5)$$

In Equations (4) and (5), v_1 and v_2 are auxiliary functions obeying the postulated linear systems; Equation (4) play the same role as Equation (2), whereas Equation (5) determine the temporal evolution of the functions v_1 and v_2 . (The evolution equation associated with the auxiliary function v for the KdV equation was not given above.) The method establishes that the functions $q = q(x, t)$ and $r = r(x, t)$ satisfy nonlinear equations when the (yet to be determined) functions A , B , C , and D are properly chosen.

The key to this approach is to make Equations (4) and (5) compatible, that is, set the x -derivative of v_{1t} equal to the t -derivative of v_{1x} . In other words, we set the x -derivative of the right-hand side of Equations (5) equal to the t -derivative of the right-hand side of Equations (4). The result of this calculation yields the following equations for A , B , C , and D :

$$\begin{aligned} A_x &= qC - rB, \\ B_x + 2i\zeta B &= q_t - 2Aq, \\ C_x - 2i\zeta C &= r_t + 2Ar, \\ D &= -A. \end{aligned} \quad (6)$$

In Ablowitz et al. (1973, 1974; see also Ablowitz & Segur, 1981), methods to solve these equations are described. The simplest procedure is to look for finite

power series expansions such as $A = \sum_{i=0}^N \zeta^i A_i$ and similarly for B and C .

For example, with $N = 2$, we find with $r = \mp q^*$ that the nonlinear Schrödinger equation (3) with $\sigma = \pm 1$ is a necessary condition. In this case there are 11 equations for the nine unknowns $\{A_i, B_i, C_i\}$, $i = 0, 1, 2$, and the remaining two equations determine the nonlinear evolution equations for q and r (in this case NLS when $q = \mp r^*$).

With $N = 3$ and $r = -1$, we find that q must satisfy the KdV equation. Also, with $r = \mp q$, the modified KdV equation

$$q_t \pm 6q^2 q_x + q_{xxx} = 0 \quad (7)$$

results.

If we look for expansions containing inverse powers of ζ , additional interesting equations can be obtained. For example, postulating $A = a/\zeta$, $B = b/\zeta$, $C = c/\zeta$ results in the sine-Gordon and sinh-Gordon equations

$$u_{xt} = \sin u, \quad (8)$$

$$u_{xt} = \sinh u, \quad (9)$$

where $q = -r = -u_x/2$ in Equation (8) and $q = r = u_x/2$ in Equation (9). The sine-Gordon equation has been known to be an important equation in the study of differential geometry since the 19th century (cf. Bianchi, 1902), and it has found applications in the 20th century as models for dislocation propagation in crystals, domain walls in ferromagnetic and ferroelectric materials, short-pulse propagation in resonant optical media, and magnetic flux propagation in long Josephson junctions, among others.

Thus, a number of physically interesting nonlinear wave equations are obtained from the above formalism. In Ablowitz et al. (1973, 1974; see also Ablowitz & Segur, 1981), it was further shown as to how this approach could be generalized to a class of nonlinear equations described in terms of certain nonlinear evolution operators that were subsequently referred to in the literature as recursion operators.

Further, the whole class of nonlinear equations with rapidly decaying initial data on $-\infty < x < \infty$ was shown to be linearized via direct and inverse scattering methods. Special soliton solutions are associated with the discrete spectrum of the linear operator (4), and via (5) the discrete eigenvalues were shown to be invariants of the motion. In subsequent years, asymptotic analysis of the integral equations yielded the long-time behavior of the continuous spectrum, which in turn showed the ubiquitous role that the Painlevé equations play in integrable systems (cf. Ablowitz & Segur, 1981).

Because this formulation is analogous to the method of Fourier transforms, the method was termed the inverse scattering transform or simply the IST.

ADIABATIC INVARIANTS

Adiabatic invariants, denoted by I , are approximate constants of motion of a given dynamical system (not necessarily Hamiltonian), which are approximately preserved during a process of slow change of the system's parameters (denoted by λ). This change is on a time scale T , which is supposed to be much larger than any typical dynamical time scale such as traversal time or the period of the shortest periodic orbits.

This is an asymptotic statement, in the sense that the adiabatic invariants are better preserved, the slower the driving of the system. In other words, the switching function $\lambda = \lambda(t)$ varies more slowly on the typical evolutionary time scale T , and the preservation is perfect in the limit $T \rightarrow \infty$.

The important point is that while the system's parameters $\lambda(t)$ and their dynamical quantities such as the total energy and angular momentum can change by arbitrarily large amounts, their combination involved in the adiabatic invariant I is preserved to a very high degree of accuracy, and this allows us to calculate changes of important quantities in dynamical systems. Examples arise in celestial mechanics, in other Hamiltonian systems, and in the motion of charged particles in magnetic and electric fields.

The accuracy of preservation can be calculated in systems with one degree of freedom and is exponentially good with T if the switching function $\lambda(t)$ is analytic (of class C^∞); that is to say, the change of the adiabatic invariant ΔI is of the form

$$\Delta I = \alpha \exp(-\beta T), \quad (1)$$

where α and β are known constants. If, however, the switching function $\lambda(t)$ is only of class C^m (m -times continuously differentiable), then the change of the adiabatic invariant ΔI during an adiabatic change over a time period of length T is algebraic only, namely

$$\Delta I = \alpha T^{-(m+1)}. \quad (2)$$

In both cases, $\Delta I \rightarrow 0$ as $T \rightarrow \infty$.

The fact that the evolutionary time scale T is large compared to the typical shortest dynamical time scales (average return time, etc.) suggests the averaging method or the so-called averaging principle. Here the long-term evolution (adiabatic evolution) of the system can be calculated by replacing the actual dynamical system with its averaged correspondent, obtained by averaging over the shortest dynamical time scales (the fast variables). Such a procedure is well known, for example, in celestial mechanics where the secular effects of the third-body perturbations of a planet are obtained by averaging the perturbations over one revolutionary period of the perturbors. This was done by Carl Friedrich Gauss

in 1801 in the context of studying the dynamics of planets.

The adiabatic invariants can be easily calculated in one-dimensional systems and in completely integrable systems with N degrees of freedom. Something is known about the ergodic Hamiltonian systems, while little is known about adiabatic invariants in mixed-type Hamiltonian systems (with divided phase space), where for some initial conditions in the classical phase space, we have regular motion on invariant tori and irregular (chaotic) motion for other (complementary) initial conditions.

One elementary example is the simple (mathematical) pendulum, of point mass m and of length l with the declination angle φ , described by the Hamiltonian

$$H = \frac{p_\varphi^2}{2ml^2} - mgl \cos \varphi, \quad (3)$$

where $p_\varphi = ml^2\dot{\varphi}$ is the angular momentum. For small oscillations $\varphi \ll 1$, around the stable equilibrium $\varphi = 0$. It is described by the harmonic Hamiltonian

$$H' = \frac{p_\varphi^2}{2ml^2} + \frac{mgl}{2} \varphi^2. \quad (4)$$

Here the angular oscillation frequency is $\omega = 2\pi\nu = \sqrt{g/l}$, where ν is the frequency and g is the gravitational acceleration. We denote the total energy of the Hamiltonian H' by E . Paul Ehrenfest discovered that the quantity $I = E/\omega$ is the adiabatic invariant of the system, so the change of $E(t)$ on large time scales $T \gg 1/\nu$ is such that $I = E(t)/\omega(t)$ remains constant. Therefore, if for example the length of the pendulum $l = l(t)$ is slowly, adiabatically changing, then the energy of the system will change according to the law

$$E = E_0 \sqrt{\frac{l_0}{l}}, \quad (5)$$

where E_0 and l_0 are the initial values and E and l the final values of the two variables. One can easily show that the oscillation amplitude φ_0 changes as $l^{-3/4}$ as the length l changes. This is an elementary example of a dynamically driven system in which the change of energy E can be very large, as is the change of ω , but $I = E/\omega$ is a well-preserved adiabatic invariant; in fact, it is exponentially well preserved if the switching function $\lambda(t)$ is analytic.

More generally, for Hamiltonian systems $H(q, p, \lambda)$ with one degree of freedom, whose state is described by the coordinate q and canonically conjugate momentum p in the phase space (q, p) , and $\lambda = \lambda(t)$ is the system's parameter (slowly changing on time scale T), one can show that the action integral

$$I(E, \lambda) = I(E(t), \lambda(t)) = \frac{1}{2\pi} \oint p \, dq \quad (6)$$

is the adiabatic invariant of the system, where the contour integral is taken at a fixed total energy E and a fixed value of λ . In this case, $2\pi I$ is interpreted as the area inside the curve $E = \text{const.}$ in the phase plane (q, p) . The accuracy is exponentially good if $\lambda(t)$ is an analytic function and algebraic if it is of class C^m . Moreover, the theorem holds true only if the frequency ω is nonzero.

This implies that a passage through a separatrix (in the phase space of a one-dimensional system) is excluded because $\omega = 0$; thus a different approach is necessary with a highly nontrivial result. When crossing a separatrix of a one-dimensional double potential well from outside in an adiabatic way going inside, a bifurcation takes place, and the capture of the trajectory in either of the two wells is possible with some probabilities. These probabilities can be calculated quite easily, and the spread of the adiabatic invariant ΔI after such a passage can also be calculated, but this is more difficult. Important applications are found in celestial mechanics, where an adiabatic capture of a small body near a resonance with a planet can take place; in plasma physics; and in quantum mechanics of states close to the separatrix (in the semiclassical limit).

This is an interesting result, because I is precisely that quantity which according to the “old quantum mechanics” of Bohr and Sommerfeld has to be quantized, that is, made equal to an integer multiple of Planck’s constant $\hbar$. Of course, the old quantum mechanics is generally wrong, but it can be a good approximation to the solution of the Schrödinger equation. Even then, strictly speaking, the quantization condition in the sense of EBK or Maslov quantization, must be written in the form

$$I = \frac{1}{2\pi} \oint p dq = \left(n + \frac{\alpha}{4}\right) \hbar, \quad (7)$$

where $n = 0, 1, 2, \dots$ is the quantum number and α is the Maslov index, that is, the number of caustics (projection singularities) round the cycle $E = \text{const.}$ in the phase plane. For smooth systems with quadratic kinetic energy, it is typically $\alpha = 2$. Thus, at this semiclassical level, we have the semiclassical adiabatic invariant, stating that in one-dimensional systems under an adiabatic change, the quantum number (and thus the eigenstate) is preserved. This agrees with the exact result in the theory of the Schrödinger equation in quantum mechanics. Round a closed loop in a parameter space, a quantum system returns to its original state, except for the phase. (This closed-loop phase change is essentially the so-called Berry’s phase.)

The method of averaging can also be used in N -dimensional Hamiltonians $H = H(q, p)$, where q and p are N -dimensional vectors, but it works only in two extreme cases: the integrable case and the ergodic case.

In a classical integrable Hamiltonian system we have N analytic, global, and functionally independent

constants of motion $A_i = A_i(q, p)$, $i = 1, 2, \dots, N$, pairwise in involution; that is, all Poisson brackets $\{A_i, A_j\}$ vanish identically everywhere in phase space. The orbits in phase space are then confined to an invariant N -dimensional surface, and according to the Liouville–Arnol’d theorem the topology of these surfaces must be the topology of an N -dimensional torus. Then an action integral $I = (1/2\pi) \oint p \cdot dq$ along a closed loop on a torus will be zero if the loop can be continuously shrunk to a point on the torus. But there are loops that cannot be shrunk to a point due to the topology of the torus. Then the integral I is different from zero, otherwise its value does not depend on the particular loop, so in a sense it is a topological invariant of the torus. On an N -dimensional torus, there are N such independent elementary closed loops C_i , $i = 1, 2, \dots, N$. The integrals that we call simply actions or action variables

$$I_i = \frac{1}{2\pi} \oint_{C_i} p \cdot dq \quad (8)$$

are then the most natural momentum variables on the torus, whilst angle variables Θ specifying the position on the torus labeled by I can be generated from the transformation

$$\Theta = \frac{\partial S(I, q)}{\partial I}, \quad (9)$$

where $S = \int p \cdot dq$ is an action integral on the torus.

Applying the averaging principle (the method of averaging), one readily shows that for an integrable system the actions I are N adiabatic invariants, provided the system is nondegenerate, which means that the frequencies

$$\omega = \frac{\partial H}{\partial I} \quad (10)$$

on the given torus are not rationally connected; that is to say, there is no integer vector k such that $\omega \cdot k = 0$. The problem is that during an adiabatic process the frequencies ω will change, and therefore, strictly speaking, there will be infinitely many points of $\lambda = \lambda(t)$, where $\omega \cdot k = 0$, which will, strictly speaking, invalidate the theorem. However, it is thought that if the degree of resonances or rationality conditions $\omega \cdot k = 0$ is of a very high order, meaning that all components of k are very large, then the adiabatic invariants I_i will be quite well preserved. But low-order resonances (rationality conditions) must be excluded. The details of such a process call for further investigation.

When the N actions I_i of an integrable system are quantized in the sense of Maslov, as explained above in the one-dimensional case, we again find agreement, at this semiclassical level, with quantum mechanics: in a family of integrable systems, all N quantum numbers and the corresponding eigenstates are preserved under an adiabatic change.

Another extreme of classically ergodic and thus fully chaotic systems has been considered already by Hertz. He found that in such ergodic Hamiltonian systems the phase space volume enclosed by the energy surface $H(\mathbf{q}, \mathbf{p}) = E = \text{constant}$ is the adiabatic invariant, denoted by

$$\Omega(E) = \int_{H(\mathbf{q}, \mathbf{p}) \leq E} d^N \mathbf{q} d^N \mathbf{p}. \quad (11)$$

Of course, here it is required that while the system's parameter $\lambda(t)$ is slowly changing, the system itself must be ergodic for all $\lambda(t)$. Sometimes, this condition is difficult to satisfy, but sometimes it is easily fulfilled. Examples are the stadium of Bunimovich with varying length of the straight line between the two semicircles, or the Sinai billiard with varying radius of the circle inside a square. For an ergodic two-dimensional billiard of area $\mathcal{A}$ and point mass m , we have

$$\Omega(E) = 2\pi m \mathcal{A} E. \quad (12)$$

Therefore, when $\mathcal{A}$ is adiabatically changing, the energy E of the billiard particle is changing reciprocally with $\mathcal{A}$. Diminishing $\mathcal{A}$ implies increasing E , and this can be interpreted as work being done against the "pressure" of only one particle, if we define the pressure as the time average of the momentum transfer at collisions with the boundary of our ergodic billiard. There is a formalism to proceed with this analysis close to the thermodynamic formalism, as derived from statistical mechanics, except that here we are talking about time averages rather than phase averages of classical variables.

Again, this general result for ergodic systems is interesting from the quantum point of view because $\mathcal{N} = \Omega(E)/(2\pi\hbar)^N$ is precisely the number of energy levels below the energy E in the semiclassical limit of very large $\mathcal{N}$, which is known as the Thomas–Fermi rule. It is the number of elementary quantum Planck cells inside the volume element $H(\mathbf{q}, \mathbf{p}) \leq E$. Indeed, quantum mechanically, the eigenstate and the (energy counting sequential) main quantum number $\mathcal{N}$ are preserved under an adiabatic change.

In case of a mixed-type Hamiltonian system, which is a typical case in nature, adiabatic theory is in its infancy. Moreover, in three or higher degrees of freedom, we have universal diffusion on the Arnol'd web, which is dense on the energy surface, even for KAM-type Hamiltonian systems that are very close to integrability, like our solar planetary system. On the Arnol'd web we have diffusional chaotic motion, and there is a rigorous theory by Nekhoroshev giving a rigorous upper bound to the diffusion rate in such a case. However, when compared with numerical calculations, it is found that the diffusion rate is many orders of magnitude smaller than the Nekhoroshev limit. In other words, the actual diffusion time is much longer than estimated by Nekhoroshev, implying that there we have

some approximate adiabatic invariant for long times, but not very long times.

ALFVÉN WAVES

The essence of Hannes Alfvén's contributions to cosmic and laboratory plasmas is his idea of combining electromagnetics and hydrodynamics (Alfvén, 1942), thus introducing the new concept of magnetohydrodynamics (MHD). Electromagnetic waves associated with the motion of conducting liquids in magnetic fields, now known as Alfvén waves, were first observed experimentally (Lundquist, 1949; Lehnert, 1954). Later on, waves of this nature have turned out to be fundamental constituents of numerous phenomena in all parts of the universe (Fälthammar, 1995; Wilhelmsson, 2000). In the pioneering experiments, liquid mercury was used by Lundquist, and liquid sodium by Lehnert, who achieved higher electrical conductivity and lower density, leading to a higher Lundquist number (lower damping). Alfvén used his early results to give a possible explanation for sunspots and the solar cycle (periodicity in the Sun's activity) (Alfvén, 1942). Alfvén noticed that the Sun has a general magnetic field and that solar matter is a good conductor, thus fulfilling idealized requirements for the notion of an electromagnetic wave in a gaseous conductor or plasma.

At a very early age, Alfvén was given a copy of a popular astronomy book by Camille Flammarion, which greatly stimulated his lifelong interest in astronomy and astrophysics. His early experiences building radio receivers at the school radio club were also important for his later activities. Interestingly, another great scientist, Albert Einstein, received a small compass as a present when he was five years old, which

entirely absorbed his interest. He asked everybody around him what a magnetic field was and what gravity was, and later on in his life he admitted that this early experience might have influenced his lifelong scientific activities. Other similarities between the two scientists were that in their professional work both Einstein and Alfvén were very creative individualists, striving for simplicity of their solutions, and being skilled in many areas, they often looked at problems with fresh eyes. Both received Nobel Prizes in physics: Einstein in 1922, Alfvén in 1970.

The simplest form of an Alfvén wave, a propagation of an electromagnetic wave in a highly conducting plasma, was first rejected by critics on the grounds that it could not be correct, otherwise it would already have been discovered by Maxwell. Furthermore, experiments had been performed with magnetic fields and conductive media by Ampère and others long ago. Nevertheless, “The Alfvén wave, in fact, is the very foundation on which the entire structure of magnetohydrodynamics (MHD) is erected. Beginning from a majestic original simplicity, it has acquired a rich and variegated character, and has ended up dictating most of the low-frequency dynamics of magnetized plasmas” (Mahajan, 1995).

To visualize the interaction between the magnetic field and the motion of the conductive fluid, one may use an analogy with the theory of stretched strings to obtain a wave along the magnetic lines of force with a velocity v_A , where

$$v_A^2 = \frac{B^2}{\mu_0 \rho} \quad (1)$$

and ρ is the mass density of the fluid, μ_0 is the permittivity, and B is the magnetic field.

The variations in velocity and current are mutually perpendicular and the magnetic field variations are in the direction of the fluid velocity variations, all variations being perpendicular to the direction of propagation. One may say that the variations of the magnetic field lines are frozen to those of the fluid motion, as can be deduced from electromagnetic equations, together with the hydrodynamic equation for the case of an incompressible fluid of infinite conductivity. The Alfvén wave is a low-frequency wave ($\omega < \omega_{ci}$, ω_{ci} being the ion cyclotron frequency) for which the displacement current is negligible. In fact, there are two types of Alfvén waves, for which

$$\omega/k_{\parallel} = v_A \text{ (torsional or shear wave)} \quad (2)$$

and

$$\omega/k = v_A \text{ (compressional wave)} \quad (3)$$

where ω is the frequency, $k^2 = k_{\parallel}^2 + k_{\perp}^2$, with $k_{\parallel}$ and $k_{\perp}$ being the wave numbers along and perpendicular to the magnetic field. For the shear wave, the frequency

depends only on $k_{\parallel}$ and not on $k_{\perp}$, which has profound consequences and leads to a continuous spectrum (Mahajan, 1995).

For determining plasma stability and in selecting schemes for plasma heating and current drive in fusion plasma devices, the understanding of Alfvén wave dynamics is of great importance and has led to a vast literature. Nonlinear effects are of relevance to large-amplitude disturbances frequently observed in laboratory and space plasmas (Wilhelmsson, 1976). The formation and propagation of Alfvén vortices with geocosmophysical and pulsar (electron-positron plasma) applications are just two examples. Alfvén waves have also found interesting applications in solid-state plasmas in semiconductors as well as in metals and semimetals. Such studies have resulted in refined methods of measuring magnetic fields.

It is often said that the universe consists 99% of plasma. Alfvén used to say that it seems as if only the crust of the Earth is not plasma. In the mid-1960s, this author gave a talk at the Royal Institute of Technology in Stockholm about plasmas in solids (electrons and holes), which Hannes Alfvén himself attended. Among other things, the talk described recent observations of Alfvén waves in such plasmas, and Alfvén said: “Ah, they are here also. How interesting, I did not know that.”

It was not until the middle of the 20th century that more intensive investigations on Alfvén waves in space and laboratory plasmas began. The slow development of the field of space plasmas was possibly because many physicists were not acquainted with the fact that electric currents can be distributed in large volumes and magnetic fields in such volumes can be present. Since then, the gigantic laboratory of the universe from the aurora originating in the Earth’s magnetosphere to quasars at the rim of the universe has attracted immense interest with regard to Alfvén waves.

When propagating in inhomogeneous plasmas, for example, in the magnetosphere, the Alfvén wave experiences many interesting phenomena, including mode coupling, resonant mode conversion, and resonant absorption. We now know that shear Alfvén waves lie behind the phenomena of micropulsations in the geomagnetic field and also acceleration of particles. Micropulsations were detected a hundred years ago with simple magnetometers on the ground. It took more than 50 years before it was understood that they were related to the magnetosphere. Solar physics is another fascinating field where Alfvén waves occur, giving rise to sunspots (Alfvén, 1942). The vast amount of energy exhibited in eruptions of particles on the solar surface, originating in the interior of the Sun, is probably transported by Alfvén waves. These also play a role in heating the solar corona. Alfvén waves were first identified in the solar wind by means of spacecraft measurements by the end of the 1960s. They also occur in the exosphere of comets. A new and promising area of research

is laboratory astrophysics using high-intensity particle and photon beams that may shed light on superstrong fields in plasmas.

For applications to confinement and heating of fusion plasmas, for example, in Tokamak devices, shear Alfvén waves have been studied in toroidal plasmas, accounting for nonuniform plasmas in axisymmetric situations. It is believed that the remaining exciting challenges lie in the area of nonlinear physics of shear Alfvén waves and associated particle dynamics and anomalous losses of α particles in a deuterium-tritium plasma. Collective modes in inhomogeneous plasmas as well as energy and particle transport in plasmas with transport barriers are of paramount importance for the design of a future Tokamak power plant (Parail, 2002).

Nonlinear transport processes in laboratory and cosmic plasmas have much in common (Wilhelmsson, 2000; Wilhelmsson & Lazzaro, 2001). Similarities (and discrepancies) could be highly indicative and beneficial for an improved understanding of specific phenomena as well as for plasma dynamics in general—possibly even for describing the evolution of the universe (Wilhelmsson, 2002).

ALGORITHMIC COMPLEXITY

The notion of complexity as an object of scientific interest is relatively new. Prior to the 20th century, the main concern was that of simplicity, with complexity being the denigrated opposite. This idea of simplicity has had a long history enshrined in the dictum of the 14th-century Franciscan philosopher, William of Occam, that “pluritas non est ponenda sine necessitate” [being is not multiplied without necessity], and passed on simply as “Occam’s razor,” or more prosaically, “keep it simple” (Thorburn, 1918).

Indeed, the razor has been invoked by such notables as Isaac Newton and, in modern times, Albert Einstein and Stephen Hawking to justify parsimony in the adoption of physical principles. Although the dictum has proved its usefulness as a support for many scientific theories, the last century witnessed a gradual concern for simplicity’s complement. Implicit was a recognition that beyond logical partitions was a need to quantify the simple/complex continuum. Perhaps the first milestone on the road to quantifying complexity came with Claude Shannon’s famous information entropy in the late 1940s. Although it was not specifically developed as a complexity measure, the information connection made by Warren Weaver soon provided an impetus for sustained interest in information as a unifying concept for complexity (Weaver, 1948).

Shannon approached information as a statistical measure of receiving a message (Shannon, 1948): if $p_1, p_2, \dots, p_N$ are the probabilities of receiving messages $m_1, m_2, \dots, m_N$, then the information carried is defined by

$$I = - \sum_i^N p_i \log_2 p_i. \quad (1)$$

Information is typically referred to as a measure of surprise; that is, the more unlikely a message, the more information it contains. To some degree, information is related to the notion of randomness in that the more regular (less complex, less random) something is, the less surprise is available. A simple calculation of this entropy demonstrates that the maximum of the function is achieved when all probabilities are equal. Shannon had a measure of capacities of a communication channel as his goal and did not concern himself with individual objects of the messages. Nonetheless, the quantification in terms of probabilities provided a basis for viewing complexity.

This theme was soon independently taken up by Ray Solomonoff (1964), Andrey Kolmogorov (1965),

and Gregory Chaitin (1966). In a sense, Somolonoﬀ was looking for a way to measure the eﬀect of Occam's razor; that is, how can one measure objectively the simplicity of a scientiﬁc theory? Kolmogorov and Chaitin, on the other hand, were interested in a measure of complexity of individual objects, as opposed to Shannon's average. This Kolmogorov–Chaitin complexity has come to be known variously as algorithmic complexity, algorithmic entropy, and algorithmic randomness, among other designations. Both Kolmogorov and Chaitin were interested in binary number strings as objects and the ability to deﬁne the complexity of a string in terms of the shortest algorithm that prints out the string. Again, regularity and randomness is involved (Gammaman & Vovk, 1999). Consider, for example, the simple bit string, 1010101010, . . . ; the minimal program to write the string requires only the pattern 10, the length of the string, and the “repeat, write” instructions, or

$$K(s) = \min\{|p| : s = C_T(p)\}, \quad (2)$$

where $K(s)$ is the Kolmogorov complexity of the string, $|p|$ is the program length in bits, and $C_T(p)$ is the result of running program p on a universal Turing machine T .

Clearly, the recognition that patterns play an important role in deﬁning complexity re-emphasized their importance in terms of data compression. In the early 1950s, David Huffman recognized their importance, and algorithmic complexity reaffirmed their utility with the ascendancy of computers and their demand for storage space (Huffman, 1952). Thus, numerous coding schemes were developed to take advantage of the fact that a simple algorithm can compress long data streams based upon the idea that recurrent patterns exist.

The eﬀorts of Somolonoﬀ, Kolmogorov, and Chaitin spawned numerous alternative measures of complexity, often seeking to address identiﬁed deﬁciencies in the deﬁnitions (Shalizi & Crutchfield, 2001). Among the deﬁciencies pointed out were the following: (i) Complexity is deﬁned in terms of randomness—it is maximized by random strings. Is this what is really sought? (ii) Complexity is uncomputable, since there is no algorithm to compute it on a universal computing machine. (iii) Complexity does not provide information regarding structural patterns or organizations that have the same amount of disorder.

These questions were compounded by the expanding ﬁeld of nonlinear dynamics. Kolmogorov's earlier entropy (1958)—developed to determine the rate of information creation—were among the invariants used to distinguish chaotic systems and an inferred complexity. Moreover, the description of physical dynamical systems became an additional issue (Zurek, 1989). Physical processes were typically described

along the continuum of two extremes: periodic or random. However, both such systems are simply described, one by a recurrent pattern and the other by a statistical description. While information is high in a random system, it is low in a periodic process. Amalgams of two such processes might require considerable computational eﬀort, yet no metric suﬃciently expressed this. Certainly, such combined processes (random and periodic) may exhibit moderate information but the most concise description may be quite complex.

Some of these diﬃculties have been addressed with varying degrees of acceptance (Wakerberger et al., 1994). Increasingly, however, it appears that the question is evolving along two diﬀerent lines: a formal approach (rules) with its main ramifications redounding to mathematics and computer science and a physical approach (equations) dealing with the characterization of systems.

Both approaches have in common the emphasis on the reconstruction (prediction) of an observed system and on the need to give the most parsimonious recipe for generating the studied entity. The metrics of complexity is thus expressed in terms of program lines for the mathematics-oriented option and in dimensionality for the physics-oriented deﬁnition, but there is the same basic notion of complexity as the inverse of compressibility of a given object (Boﬀetta et al., 2002).

This notion of compressibility has an immediate translation in terms of both multidimensional statistics and technology. In multidimensional statistics, the compressibility of a given data set corresponds to the percentage of explained variance by the optimal (generally in a least-squares sense) model of the data. More generally, something can be compressed if there exists some sort of correlation structure linking the diﬀerent portions of a system, the existence of such correlations implying that the information about one part of the system is implicit in another part. Thus, all the information is not needed to reconstruct the entire system. It is evident how this concept corresponds to the cognate concept of redundancy, bringing us back to the notion of entropy (Giuliani et al., 2001).

Clearly, the diverse algorithms designed to measure complexity suggest a commonality. The question remains as to whether one metric is suﬃcient for its characterization.

ANDERSON LOCALIZATION

Anderson localization is a phenomenon associated with the interference of waves in random media. Although

Philip Anderson's original publication (Anderson, 1958) was actually motivated by experiments on the propagation of spin-waves in random magnets, the greatest application of the concept has been the study of electrical transport phenomena in metals and semiconductors. Over the past 10 years, more attention has been focused on other wave phenomena in random media, particularly optical phenomena.

Our current understanding of electronic transport in metals and semiconductors is based on the Schrödinger equation for the wave function of conduction electrons of the form

$$-\frac{\hbar^2}{2m^*}\nabla^2\psi(\mathbf{r}) + [U(\mathbf{r}) + V(\mathbf{r})]\psi(\mathbf{r}) = E\psi(\mathbf{r}),$$

where $U(\mathbf{r})$ is a periodic potential representing the regular lattice in the solid and $V(\mathbf{r})$ is a random function of position, which represents the presence of impurities in the system. In the absence of the random potential, the allowed energies of such an electron fall within a series of bands separated by energy gaps. The eigenfunctions in the absence of the random potential are all of the form $e^{i\mathbf{k}\cdot\mathbf{r}}u_{j,\mathbf{k}}(\mathbf{r})$ where the wavevector $\mathbf{k}$ lies within the first Brillouin zone, j labels the energy bands and the Bloch function, $u_{j,\mathbf{k}}(\mathbf{r})$, has the periodicity of the regular potential, U . Such states are *extended* in the sense that their support covers the entire system and hence they can contribute to electrical conduction.

The eigenstates of an electron subject to a random potential may be of two types. Some are extended, although there may be strong local modulations in the amplitude. These states can contribute to electrical conduction through the material, even at zero temperature, as they connect the two ends of a sample. Other states, however, are localized in that their amplitude vanishes exponentially outside a specific finite region. These states are referred to as *Anderson localized* and can only contribute to conduction via thermal activation.

One can understand the existence of localized states by considering the low-energy states of an electron moving in a very rough, random potential, $V(\mathbf{r})$ (Lee & Ramakrishnan, 1985). The lowest energy states will be those bound to very deep troughs in the potential function. The mixing between states localized in different wells will be very weak because states with significant spatial overlap will have very different energies, while states with similar energies are spatially well separated so that the wave function overlaps are exponentially small.

The scale on which the wave functions of localized states decay to zero defines the localization length ξ , which depends on the energy of the state and the strength of the disorder. The balance between extended and localized states depends on the strength of the disorder and the spatial dimensionality of the

Figure 1. A schematic plot of the density of states showing a single disorder broadened band for a 3-d system. The states in the band center are extended while those in the tails are localized (shaded regions); the mobility edges between the two types of state are marked.

system. In a one-dimensional (1-d) system, all of the electronic eigenstates are strongly localized by any amount of disorder. In two dimensions, it is believed that all states are actually localized, but that the localization length can be very long in the center of a band. The application of a strong magnetic field to a disordered 2-d electron system, such as may be formed at a semiconductor heterojunction at low temperature, causes the conduction band to break up into a sequence of disorder broadened Landau bands, each with an extended state at its center—an essential feature of the quantum Hall effect. In three dimensions, the eigenstates at the center of a band are truly extended while those in the low- and high-energy tails are localized. It is believed that there are two well-defined critical energies within the band at which the nature of the states changes so that localized and extended states do not co-exist at a given energy.

The critical energies are usually referred to as mobility edges because the zero-temperature conductance of the system will be zero when the Fermi energy lies in the regime of localized states but nonzero in the extended regime (see Figure 1). The location of the mobility edges depends on the strength of the disorder—in very clean systems, only the states in the tails of a band will be localized while in a very dirty system the mobility edges may meet in the band center so that all states are localized. The behavior at the mobility edge has been studied by performing experiments on a series of devices with increasing amounts of disorder. The transition between metallic (conducting) and insulating behavior is closely analogous to other phase transitions. Mott (1973) supposed that this metal-insulator transition was first order, with the conductivity jumping from a fixed finite value, $\sigma_{\min}$, to zero. In 1979, a renormalization group analysis was carried out by the so-called “gang of four,” based on earlier scaling argu-

ments by Thouless and co-workers (Thouless, 1974), which favored a continuous metal-insulator transition for 3-d systems (Abrahams et al., 1979). The discussion of the change in nature of the states from extended to localized in terms of a zero-temperature quantum phase transition has been very fruitful. In this description, the localization length, ξ , plays the same role as the correlation length for fluctuations in a thermal transition. It is supposed that ξ diverges at the mobility edges according to a universal power law

$$\xi \sim |E - E_c|^{-\nu}.$$

Numerical evidence indicates that the value of the exponent is indeed universal and has the value $\nu \sim 1.6$.

Although the underlying physics of Anderson localization is that of linear waves in random media, the discussion can be recast in terms of nonlinear models without disorder, which are in the same family of statistical field theories used to describe thermal phase transitions, specifically nonlinear sigma models (Efetov, 1997). This has led to the notion that the spatial variation of the wave functions of states at the mobility edge displays a multifractal character.

The application of these ideas to other wave phenomena in random media has been slower. It is much harder to observe strong localization in bosonic and classical wave systems, but recently much experimental work has been carried out on optical and acoustic localization (see John (1990) for a good introduction). This work shows that Anderson localization is not an essentially quantum mechanical effect but is ubiquitous for wave propagation in random media. Similarly, the interplay between the physics of randomly disordered systems and quantum chaos is also proving very rich and fruitful (Altshuler & Simons, 1994).

There are a number of other mechanisms whereby wave excitations may become spatially localized. The propagation of excitations within macromolecules, for example, may become localized both because of interference effects associated with “random” changes in structure and also because of self-trapping effects associated with nonlinearity in the wave equation for these modes. In the case of electrons in solids, electronic excitations may become localized both by random variations in potential and by interaction effects that give rise to the so-called Mott transition. Such interaction effects are responsible for the phenomenon of Coulomb blockade observed in semiconductor nanostructures.

ANOSOV AND AXIOM-A SYSTEMS

Two classes of dynamical systems exhibiting chaotic behavior were axiomatically defined and systematically studied for the first time in the 1960s. Previous studies had concentrated on more specific situations. Axiom-A systems were introduced by Stephen Smale in his seminal paper (Smale, 1967). Anosov systems, which are a special case of Axiom-A systems, were studied independently in Moscow around the same period. Today, Anosov and Axiom-A systems are valued as idealized models of chaos: while the conditions defining Axiom-A are too stringent to include many real-life examples, it is recognized that they have features shared in various forms by most chaotic systems.

Definitions

First, we give the definitions in the discrete-time case.

Let f be a smooth invertible map (for basic notions, See **Phase space**). A compact invariant set of f is said to be *hyperbolic* if at every point in this set, the tangent space splits into a direct sum of two subspaces E^u and E^s with the property that these subspaces are invariant under the differential df , that is, $df(x)E^u(x) = E^u(f(x))$, $df(x)E^s(x) = E^s(f(x))$, and that df expands vectors in E^u and contracts vectors in E^s .

If $F^u = \{0\}$ in the definition above, then the invariant set is made up of attracting fixed points or periodic orbits. Similarly, if $E^s = \{0\}$, then the orbits are repelling. If neither subspace is trivial, then the behavior is locally “saddle-like,” that is to say, relative to the orbit of a point x , most nearby orbits diverge exponentially

fast both in forward and in backward time. This is why hyperbolicity is a mathematical notion of chaos.

An *Anosov diffeomorphism* is a smooth invertible map of a compact manifold with the property that the entire space is a hyperbolic set.

Axiom A, which is a larger class, focuses on the part of the system that is not transient. More precisely, a point x in the phase space is said to be nonwandering if every neighborhood U of x contains an orbit that returns to U . A map is said to satisfy Axiom A if its nonwandering set is hyperbolic and contains a dense set of periodic points.

Definitions in the continuous-time case are analogous: f above is replaced by the time- t -maps of the flow, and the tangent spaces now decompose into $E^u \oplus E^0 \oplus E^s$ where E^0 , which is 1-d, represents the direction of the flow lines.

Phase Space Structures and Properties

Anosov and Axiom-A systems are defined by the behavior of the differential. Corresponding to the linear structures left invariant by df are nonlinear structures, namely stable manifolds tangent to E^s and unstable manifolds tangent to E^u .

Thus, two families of invariant manifolds are associated with an Anosov map and each one of these fills up the entire phase space; they are sometimes called the *stable* and *unstable foliations*. The leaves of these foliations are transverse at each point, forming a kind of (topological) coordinate system. The map f expands distances along the leaves of one of these foliations and contracts distances along the leaves of the other. For Axiom-A systems, one has a similar local product structure or “coordinate system” at each point in the nonwandering set, but the picture is local, and there are gaps: the stable and unstable leaves do not necessarily fill out open sets in the phase space.

In addition to these local structures, Axiom-A systems have a global structure theorem known as *spectral decomposition*. It says that the nonwandering set of every Axiom-A map can be written as $X_1 \cup \dots \cup X_r$ where the X_i are disjoint closed invariant sets on which f is topologically transitive. The X_i are called basic sets. Each X_i can be decomposed further into a finite union $\bigcup X_{i,j}$, where each $X_{i,j}$ is invariant and topologically mixing under some iterate of f . (Topological transitivity and mixing are irreducibility conditions; See **Phase space**.) This decomposition is reminiscent of the corresponding result for finite-state Markov chains.

One of the reasons why hyperbolic sets are important is their robustness: they cannot be perturbed away. More precisely, let f be a map with a hyperbolic set Λ that is locally maximal, that is, it is the largest invariant set in some neighborhood U . Then for every map g that is C^1 near f , the largest invariant set Λ' of g in

U is again hyperbolic; moreover, f restricted to Λ is *topologically conjugate* to g restricted to Λ' . This is mathematical shorthand for saying that not only are the two sets Λ and Λ' topologically indistinguishable, but the orbit structure of f on Λ is indistinguishable from that of g on Λ' .

The above phenomenon brings us to the idea of *structural stability*. A map f is said to be *structurally stable* if every map g , that is C^1 near f is topologically conjugate to f (on the entire phase space). It turns out that a map is structurally stable if and only if it satisfies Axiom A and an additional condition called *strong transversality*.

Next, we discuss the idea of pseudo-orbits versus real orbits. Letting $d(\cdot, \cdot)$ be the metric, a sequence of points $x_0, x_1, x_2, \dots$ in the phase space is called an ε -pseudo-orbit of f if $d(f(x_i), x_{i+1}) < \varepsilon$ for every i . Computer-generated orbits, for example, are pseudo-orbits due to round-off errors. A fact of consequence to people performing numerical experiments is that in hyperbolic systems, small errors at each step get magnified exponentially fast. For example, if the expansion rate is ≥ 3 , then an ε -error made at one step is tripled at each subsequent step, that is, after only $O(|\log \varepsilon|)$ iterates, the error is $O(1)$, and the pseudo-orbit bears no relation to the real one. There is, however, a theorem that states that every pseudo-orbit is shadowed by a real one. More precisely, given a hyperbolic set, there is a constant C such that if $x_0, x_1, x_2, \dots$ is an ε -pseudo-orbit, then there is a phase point z such that $d(x_i, f^i(z)) < C\varepsilon$ for all i . Thus, paradoxical as it may first seem, this result asserts that on hyperbolic sets, each pseudo-orbit approximates a real orbit, even though it may deviate considerably from the one with the same initial condition.

The shadowing orbit corresponding to a bi-infinite pseudo-orbit is, in fact, unique. From this, one deduces the following Closing Lemma: for any hyperbolic set, there is a constant C such that the following holds: every finite orbit segment $x, f(x), \dots, f^{n-1}(x)$ that nearly closes up, that is, $d(x, f^{n-1}(x)) < \varepsilon$ for some small ε , lies within $< C\varepsilon$ of a genuine periodic orbit of period n . Thus, hyperbolic sets contain many periodic points.

Examples

A large class of Anosov diffeomorphisms comes from linear toral automorphisms, that is, maps of the n -dimensional torus induced by $n \times n$ matrices with integer entries, $\det = \pm 1$, and no eigenvalues of modulus one. (See **Cat map** for a detailed example of this). We remark that due to their structural stability (nonlinear), perturbations of linear toral automorphisms continue to have the Anosov property. This remark also applies to all of the examples below. In fact, all known Anosov diffeomorphisms are

Figure 1. The horseshoe.

Figure 2. The solenoid.

topologically identical to a linear toral automorphism (or a slight generalization of these).

Geodesic flows describe free motions of points on manifolds. Let M be a manifold. Given $x \in M$ and a unit vector v at x , there is a unique geodesic starting from x in the direction v . The geodesic flow φ^t is given by $\varphi^t(x, v) = (x', v')$, where x' is the point t units down the geodesic and v' is the direction at x' . Geodesic flows on manifolds of strictly negative curvature are the main examples of Anosov flows. They were studied by Jacques Hadamard (ca. 1900) and Gustav Hedlund and Eberhard Hopf (in the 1930s) considerably before Anosov theory was developed.

Smale's *horseshoe* is the prototypical example of a hyperbolic invariant set. This map, so called because it bends a rectangle B into the shape of a horseshoe and puts it back on top of B , is shown in Figure 1. The set $\{x: f^n(x) \in B \text{ for all } n = 0, \pm 1, \pm 2, \dots\}$ is hyperbolic (See **Horseshoes and hyperbolicity in dynamical systems; Phase space**).

Finally, we mention the *solenoid* (see Figure 2, and also in the color plate section as the Smale solenoid), which is an example of an Axiom-A attractor. Here, the map f is defined on a solid torus $M = S^1 \times D_2$, where D_2 is a 2-d disk. It is easiest to describe it in two steps: first it maps M into a long thin solid torus, which is then placed inside M winding around the S^1 direction twice. The attractor is given by $\Lambda = \bigcap_{n \geq 0} f^n(M)$.

Symbolic Coding of Orbits and Ergodic Theory

An important tool for studying the orbit structure of Axiom-A systems is the *Markov partition*, constructed for Anosov systems by Sinai and extended to Axiom-A basic sets by Bowen. Given a partition $\{R_1, \dots, R_k\}$ of the phase space, there is a natural way to attach

to each point x in the phase space a sequence of symbols, namely $(\dots, a_{-1}, a_0, a_1, a_2, \dots)$ where $a_i \in \{1, 2, \dots, k\}$ is the name of the partition element containing $f^i(x)$, that is, $f^i(x) \in R_{a_i}$ for each i . In general, not all sequences are realized by orbits of f . Markov partitions are designed so that the set of symbol sequences that correspond to real orbits has Markovian properties; it is called a shift of finite type (See **Symbolic dynamics**).

The ergodic theory of Axiom-A systems has its origins in statistical mechanics. In a 1-d lattice model in statistical mechanics, one has an infinite array of sites indexed by the integers; at each site, the system can be in any one of a finite number of states. Thus, the configuration space for a 1-d lattice model is the set of bi-infinite sequences on a finite alphabet. Identifying this symbol space with the one from Markov partitions, Sinai and Ruelle were able to transport some of the basic ideas from statistical mechanics, including the notions of Gibbs states and equilibrium states, to the ergodic theory of Axiom-A systems.

The notion of *equilibrium states*, which is equivalent to Gibbs states for Axiom-A systems, has the following meaning in dynamical systems in general: given a potential function φ , an invariant measure is said to be an equilibrium state if it maximizes the quantity

$$h_\mu(f) - \int \varphi d\mu,$$

where $h_\mu(f)$ denotes the Kolmogorov–Sinai entropy of f and the supremum is taken over all f -invariant probability measures μ . In particular, when $\varphi = 0$, this measure is the measure that maximizes entropy; and when $\varphi = \log |\det(df|_{E^u})|$, it is the Sinai–Ruelle–Bowen (SRB) measure. From a physical or observational point of view, SRB measures are the most important invariant measures for dissipative dynamical systems (See **Sinai–Ruelle–Bowen measures**).

Periodic Points and Their Growth Properties

We discuss briefly some further results related to the abundance of periodic points in Axiom-A systems.

For an Axiom-A diffeomorphism f , if $P(n)$ is the number of periodic points of period $\leq n$, then $P(n) \sim e^{hn}$ where h is the topological entropy of f . That is to say, the dynamical complexity of f is reflected in its periodic behavior. An analogous result holds for Axiom-A flows.

Finally, we mention the dynamical zeta function, which sums up the periodic information of a system. In the discrete-time case, $\zeta(z) := \exp \sum_{n=1}^{\infty} P(n)z^n/n$ has been shown to be a rational function analytic on $|z| < e^{-h}$. In the continuous-time case, the zeta function is given by $\zeta(z) := \prod_{\gamma} (1 - \exp(-z l(\gamma)))^{-1}$, where the product is taken over all (nonstationary) periodic orbits γ and $l(\gamma)$ is the smallest positive period

of γ . This function is known to be meromorphic on a certain domain, but the locations of its poles, which are intimately related to correlation decay properties of the system, remain one of the yet unresolved issues in Axiom-A theory.

ARNOL'D DIFFUSION

For near-integrable Hamiltonian systems with more than two degrees of freedom, stochastic and regular trajectories are intimately co-mingled in the $2N$ -dimensional phase space. Stochastic layers in phase space exist near resonances of the motion. The thickness of the layers expands with increasing perturbation, leading to primary resonance overlap, motion across the layers, and the appearance of strong stochasticity in the motion. In the limit of weak perturbation, however, primary resonance overlap does not occur. A new physical behavior of the motion then makes its appearance: motion along the resonance layers called Arnol'd diffusion (AD). For two degrees of freedom, with a weak perturbation, two-dimensional

Figure 1. Illustration of the directions of the fast diffusion across a resonance layer and the slow diffusion along the resonance layer.

Kolmogorov–Arnol’d–Moser (KAM) surfaces divide the three-dimensional energy “volume” in phase space into a set of closed volumes each bounded by KAM surfaces, much as lines isolate regions of a plane. For $N > 2$ degrees of freedom, the N -dimensional KAM surfaces do not divide the $(2N - 1)$ -dimensional energy volume into distinct regions. Thus, for $N > 2$, in the generic case, all stochastic layers of the energy surface in phase space are connected into a single complex network—the Arnol’d web. The web permeates the entire phase space, intersecting or lying infinitesimally close to every point. For an initial condition within the web, the subsequent stochastic motion will eventually intersect every finite region of the energy surface in phase space, even in the limit as the perturbation strength approaches zero.

The merging of stochastic trajectories into a single web was proved (Arnol’d, 1964) for a specific nonlinear Hamiltonian. A general proof of the existence of a single web has not been given, but many computational examples support the conjecture. From a practical point of view, there are two major questions with respect to AD in a particular system: what is the relative measure of stochastic trajectories (fraction of the phase space that is stochastic) in the region of interest? And for a given initial condition, how fast will system points diffuse along the thin threads of the Arnol’d web?

We illustrate the motion along the resonance layer in Figure 1. A projection of the motion onto the J_1, θ_1 plane is shown, illustrating a resonance with a stochastic layer. At right angles to this plane, the action of the other coordinate J_2 is shown. If there are only two degrees of freedom in a conservative system, the fact that the motion is constrained to lie on a constant energy surface restricts the change in J_2 for J_1 constrained to the stochastic layer. However, if there is another degree of freedom, or if the Hamiltonian is time dependent, then this restriction is lifted, and motion along the stochastic layer in the J_2 direction can occur.

The diffusion rate (D) along a layer has been calculated by Chirikov (1979) for the important case of three resonances, and by Tennyson et al. (1979) for an equivalent mapping model, which they called a stochastic pump. These models predict, for a single action I corresponding to J_2 in Figure 1,

$$D = (\Delta I)^2 / t \propto e^{-A/\varepsilon^{1/2}}, \quad (1)$$

where t is the time, ε is a perturbation parameter, and $A \approx 1$. For coupling among many resonances, a rigorous upper bound on the diffusion rate (Nekhoroshev, 1977) generally overestimates the rate by orders of magnitude. Using a similar formalism with a somewhat more restrictive class of Hamiltonians, but still encompassing most physical problems, the upper bound can be improved (Benettin et al., 1985; Lochak & Neistadt, 1992) to give what they considered to be an optimal upper bound:

$$D \propto e^{-A/\varepsilon^\gamma}, \quad \gamma \approx N^{-1}. \quad (2)$$

If N is large, such an exponentially small diffusion could only hold for very small ε (specified within the theory), otherwise the exponential factor could be essentially unity. Also, an upper bound must be related to the fastest local diffusion. This may be much more rapid than an average global diffusion, which would be controlled by the portions of the phase space where the diffusion is slowest. For upper bound calculations, consult the original papers of Nekhoroshev (1977), Benettin et al. (1985), and Lochak & Neistadt (1992).

The simplest way to calculate local AD is to couple two standard maps together with a weak coupling term $\mu \sin(\theta_n + \phi_n)$, where θ_n and ϕ_n are the map phases and $\mu \ll 1$. Using the stochastic pump model, with a regular orbit (in the absence of coupling) in the (I, θ) map being driven by stochasticity in the (J, ϕ) map, the Hamiltonian of the mapping is approximated as $H \approx H_i + H_j$, with

$$H_i = I^2/2 + K_i \cos \theta + 2\mu \cos(\theta + \phi),$$

$$H_j = J^2/2 + K_j \cos \phi + 2K_j \cos \phi \cos 2\pi n, \quad (3)$$

where n is the time normalized to mapping periods. We have retained only the lowest Fourier term from the mapping frequency in the H_j equation of (3), and considered that the stochasticity in H_i is driven by the coupling. To calculate the changes in H_i per iteration due to kicks delivered by (J, ϕ) , we take the derivative

$$\begin{aligned} \frac{\partial H_i}{\partial n} &= \frac{dH_i}{dn} \\ &= \frac{d}{dn} [2\mu \cos(\theta + \phi)] \\ &\quad + 2\mu \frac{d\theta}{dn} \sin[\theta + \phi(n)]. \end{aligned} \quad (4)$$

For rotational orbits $\theta = w_i n + \theta_0$, scaling the time variable to revolutions of the map ($s = \omega_j n$), and defining the ratio of frequencies ($Q_0 = \omega_i / \omega_j = \omega_i / K_j^{1/2}$), Equation (4) is integrated to obtain

$$\Delta H_i = 2\mu Q_0 \left(\cos \theta_0 \int_{-\infty}^{\infty} \sin[Q_0 s + \phi(s)] ds + \sin \theta_0 \int_{-\infty}^{\infty} \cos[Q_0 s + \phi(s)] ds \right). \quad (5)$$

The first of the integrals in (5) integrates to zero; the second is a Mel'nikov-Arnol'd integral (Chirikov, 1979, Appendix A), which can be evaluated to give the change in ΔH_i over one characteristic half-period of the (J, ϕ) map. Squaring ΔH_i and averaging over θ_0 gives

$$\langle (\Delta H_i)^2 \rangle = 32\pi^2 Q_0^4 \mu^2 \frac{\sinh^2(\pi Q_0/2)}{\sinh^2(\pi Q_0)}. \quad (6)$$

To determine the diffusion constant D , divide $\langle (\Delta H_i)^2 \rangle$ by twice the average number of iterations in this half-period

$$\bar{T}_j = \frac{1}{\omega_j} \ln \left| \frac{32e}{w_1} \right|, \quad (7)$$

where $w_1 = \Delta H / H_{\text{separatrix}}$ is the relative energy of the edge of the stochastic region, $w_1 = 8\pi(2\pi / K_j^{1/2})^3 \times e^{-\pi^2 / K_j^{1/2}}$, and e is the base of natural logarithms. Combining (6) and (7), and using $\Delta H_i = I \Delta I$, the diffusion constant in action space can be approximated in a form that exhibits the main Q_0 scaling:

$$D \approx 16\mu^2 n Q_0^2 e^{-\pi Q_0}, \quad (8)$$

where we have assumed that $I \approx \omega_i$. Comparing (8) to (1) with $Q_0 = \omega_i / K_j^{1/2}$, we observe that $K_j \propto \varepsilon$, the perturbation parameter. The numerical results agreed well with (8) (see Lichtenberg & Aswani (1998) and references therein).

Chirikov et al. (1979) found, numerically, that one could distinguish the diffusion in a range where ε was sufficiently large and a single resonance was dominant, such that a three-resonance model scaling as in (1) holds, from a range of smaller values of ε with many overlapping weak resonances, where the scaling in (2) applies. The results of their numerical investigation demonstrated the transition between the two regimes. In another approach, the diffusion through a large number of weakly coupled standard mappings was determined numerically, with the strength of the coupling controlled in a manner such that the three-resonance model could be applied in a statistical manner to determine the diffusion rate (Lichtenberg & Aswani, 1998).

These studies indicate that the basic models can be used to determine Arnol'd diffusion in multidimensional systems if the system parameters can be sufficiently controlled. For more information on these and related topics, the reader is referred to Chirikov (1979) and to Lichtenberg & Lieberman (1991, Chapter 6).

ARTIFICIAL INTELLIGENCE

Artificial intelligence (AI) is a field of research in computer science reproducing intelligent reasoning. AI programs are mainly based on logic-oriented symbolic languages such as, for example, Prolog (Programming in Logic) or LISP (List Programming). Historically, AI was inspired by Alan Turing's question: "Can machines think?" According to the Turing test for AI, a machine is intelligent if a human user cannot distinguish whether he or she is interacting and communicating with a machine or a human being. Thus, before starting with AI, a general concept of computer and computability must be defined in computer science.

In 1936, Turing and Emil Post independently suggested the following definition of computability.

A "Turing machine" consists of: (a) a control box in which a finite program is placed, (b) a potentially infinite tape, divided lengthwise into squares, and (c) a device for scanning, or printing on one square of the tape at a time, and for moving along the tape or stopping, all under the command of the control box.

If the symbols used by a Turing machine are restricted to a stroke / and a blank *, then every natural number x can be represented by a sequence of x strokes (e.g., 3 by ///), each stroke on a square of the Turing tape. The blank is used to denote that the square is empty (or the corresponding number is zero). In particular, a blank is necessary to separate sequences of strokes representing numbers. Thus, a Turing machine computes a numerical function f with arguments $x_1, \dots, x_n$ if the machine program starts with the input tape $\dots * x_1 * x_2 * \dots * x_n * \dots$ and stops after finite steps with an output $\dots * x_1 * x_2 * \dots * x_n * f(x_1, \dots, x_n) * \dots$ on the tape. From a logical point of view, John von Neumann's general-purpose computer is a technical realization of a universal Turing machine that can simulate any kind of Turing program.

Besides Turing machines, there are many other mathematically equivalent procedures for defining computability (e.g., register machines, recursive functions) that are mathematically equivalent. According to Alonzo Church's thesis, the informal intuitive notion of an algorithm is identical to one of these equivalent mathematical concepts, for example, the program of a Turing machine.

With respect to AI, the paradigm of effective computability implies that the mind is represented by program-controlled machines, and mental structures refer to symbolic data structures, while mental processes implement algorithms. Historically, the hard core of AI was established during the Dartmouth Conference in 1956 when leading researchers, such as John McCarthy, Alan Newell, Herbert Simon, and others from different disciplines, formed the new scientific community of AI. If human thinking can be represented by an algorithm, then according to Church's thesis, it can be represented by a Turing program that can be computed by a universal Turing machine. Thus, human thinking could be simulated by a general-purpose computer and, in this sense, Turing's question ("Can machines think?") must be answered with a "yes." The premise that human thinking can be codified and represented by recursive procedures is, of course, doubtful. Even processes of mathematical thinking can be more complex than recursive functions.

The first period of AI was dominated by questions of heuristic programming, which means the automated search for human problem solutions in trees of possible derivations, controlled and evaluated by heuristics. In 1962, these simulative procedures were generalized and enlarged for the so-called General Problem Solver (GPS), which was assumed to be the heuristic

framework of human problem solving. But GPS could only solve some insignificant problems in a formalized microworld. Thus, AI researchers tried to construct specialized systems of problem solving that use the specialized knowledge of human experts.

The architecture of an "expert system" consists of the following components: knowledge base, problem-solving component (interference system), explanation component, knowledge acquisition, and dialogue component. Knowledge is the key factor in the performance of an expert system. The knowledge is of two types. The first type is the facts of the domain that are written in textbooks and journals in the field. Equally important to the practice of a field is the second type of knowledge, called heuristic knowledge, which is the knowledge of good practice and judgment in a field. It is experimental knowledge, that art of good guessing, that a human expert acquires over years of work.

Expert systems are computational models of problem-solving procedures that need symbolic representation of knowledge. Unlike program-controlled serial computers, the human brain and mind are characterized by learning processes without symbolic representations. With respect to the architecture of von Neumann computers, an essential limitation derives from the sequential and centralized control, but complex dynamical systems like the brain are intrinsically parallel and self-organized.

In their famous paper "A Logical Calculus of the Ideas Immanent in Nervous Activity" in 1943, Warren McCulloch and Walter Pitts offered a complex model of neurons as threshold logic units with excitatory and inhibitory synapses. Their "McCulloch-Pitts neuron" fires an impulse along its axon at time $t + 1$ if the weighted sum of its inputs and weights at time t exceeds the threshold of the neuron. The weights are numbers corresponding to the neurochemical interactions of the neuron with other neurons. But, in a McCulloch-Pitts network, the function of an artificial neuron is fixed for all time. McCulloch and Pitts succeeded in demonstrating that a network of formal neurons of their type could compute any finite logical expression.

In order to make a neural computer capable of complex tasks, it is necessary to find procedures of learning. A learning procedure is nothing else than an adjustment of the many weights so that the desired output vector (e.g., a perception) is achieved. The first learning neural computer was Frank Rosenblatt's "Perceptron" (1957). Rosenblatt's neural computer is a feedforward network with binary threshold units and three layers. The first layer is a sensory surface called a "retina" that consists of stimulus cells (S-units). The S-units are connected with the intermediate layer by fixed weights that do not change during the learning process. The elements of the intermediate layer are

called associator cells (A-units). Each A-unit has a fixed weighted input of some S-units. In other words, some S-units project their output onto an A-unit. An S-unit may also project its output onto several A-units. The intermediate layer is completely connected with the output layer, the elements of which are called response cells (R-units). The weights between the intermediate layer and the output layer are variable and thus able to learn.

The Perceptron was viewed as a neural computer that can classify a perceived pattern in one of several possible groups. In 1969, Marvin Minsky and Seymour Papert proved that Perceptrons cannot recognize and distinguish the connectivity of patterns, in general. The Perceptron's failure is overcome by more flexible networks with supervised and unsupervised learning algorithms (e.g., Hopfield systems, Chua's cellular neural networks, Kohonen's self-organizing maps).

In the age of globalization, communication networks such as the Internet are a tremendous challenge to AI. From a technical point of view, we need intelligent programs distributed in the nets. There are already more or less intelligent virtual organisms (agents), learning, self-organizing, and adapting to our individual preferences of information, to select our e-mails, to prepare economic transactions, or to defend against attacks of hostile computer viruses, like the immune system of our body. Although the capability to manage the complexity of modern societies depends decisively on progress in AI, we need computational ecologies with distributed AI to support human life and not human-like robots to replace it.

ARTIFICIAL LIFE

The term *artificial life* (AL) was coined in 1987 by Christopher Langton, who organized a workshop by that name in frustration with the lack of a forum

for discussing work on the computer simulation of biological systems. In Langton's characterization, AL seeks to "contribute to theoretical biology by locating life-as-we-know-it within the larger picture of life-as-it-could-be" (Langton, 1989). In other words, AL aims to use computer simulation to synthesize alternative life-like systems and, thus, find out which characteristics and principles are essential and which are merely contingent on how life happened to evolve on this planet. While other branches of biology may use simulation to understand specific mechanisms, AL is broader, more abstract, and highly interdisciplinary, in addition to implying certain ideological convictions. Chief among these is the assumption that life is a process, rather than a metaphysical substance or an atomic property of matter, which emerges in a bottom-up fashion from local interactions among suitably arranged populations of individually lifeless components.

Opinions differ on whether such artificial systems may be logically equivalent to their natural counterparts and therefore really alive, or whether they are simply life-like simulacra. The former view is called the strong AL hypothesis, to associate it with a similarly functionalist standpoint known as Strong Artificial intelligence. However, the strong position in AL is considerably more tenable than its AI analog, which fails to distinguish between emergent and explicitly predetermined sources of behavior. Related to this "strong versus weak" argument is the unresolved question of whether life is an absolute category in nature at all or simply a useful way of grouping certain phenomena.

Early History

Attempts to construct living or life-like artifacts from mechanical parts date back at least to the ancient Greeks, and we can presume that many of these experiments were motivated by questions similar to those posed today. Nevertheless, these early systems tended to employ the "if it quacks like a duck it is a duck" principle, and so were only superficially lifelike, rather than in the deeper sense presently hoped for. One of the most ingenious of these early automata was indeed a duck (or at least something that moved, ate, defecated, and quacked like one), built by Jacques de Vaucanson around 1730.

Mary Shelley's *Frankenstein* explores similar issues in a fictional context. Contrary to popular belief, Shelley's monster was apparently not made from human body parts but from raw materials (cadavers are only mentioned with regard to Frankenstein's research). These components were then imbued with the "spark of life" (which Shelley associates with electricity) in order to animate them. Her viewpoint was still partially vitalistic, but there is a link between Shelley and her

contemporary Charles Babbage, whose interpretation of intelligence (if not life itself) was more formalized, abstract, and mechanical. The mechanization of the mind continued with George Boole's logical algebra and then the work of Alan Turing and John von Neumann on automating thought processes, which led directly to the invention of the digital computer and the beginnings of artificial intelligence. It was a similar inquiry into the abstract nature of life, as distinct from mind, that prompted von Neumann's investigations into self-replicating machinery and Turing's work on embryogenesis and "unorganized machines" (related to neural networks).

Formal Methods

While complexity theory is concerned with the manner in which complex behavior arises from simple systems, AL is interested in how systems generate continually increasing levels of complexity. The most striking feature of living systems is their ability to self-organize and self-maintain—a property that Humberto Maturana and Francisco Varela have termed "autopoiesis" (Maturana & Varela, 1980). Evolution, embryogenesis, learning, and the development of social organizations are therefore the mechanisms of primary interest to AL researchers.

The key features of AL models are the use of populations of semi-autonomous entities, the coupling of these through simple local interactions (no centralized control and little or no globally accessible information), and the consequent emergence of collective, persistent phenomena that require a higher level of description than that used to describe their substrate. Conventional mathematical notation is not usually appropriate for such distributed and labile systems, and the individual computer programs are often their own best description. There are, however, a number of frequently used abstract structures and formal grammars, including the following:

Cellular automata, in which the populations are arrays of finite state machines and interactions occur between neighboring cells according to simple rules. Under the right conditions, emergent entities (such as the glider in John Conway's Game of Life) arise and persist on the surface of the matrix, interacting with other entities in computationally interesting ways.

Genetic algorithms, in which the populations are genomes in a gene pool and interactions occur between their phenotypes and some form of stressful environment. Natural selection (or sometimes human choice) drives the population to adapt and grow ever fitter, perhaps solving real practical problems in the process.

L-systems, or *Lindenmayer systems*, which provide a grammar for defining the growth of branching (often plant-like) physical structures, as insights into morphology and embryology.

Autonomous agents, which are composite code and data objects, representing mobile physical entities (robots, ants, stock market traders) embedded in a real or simulated environment. They interact locally by sensing their environment and receiving messages from other agents, giving rise to emergent phenomena of many kinds including cooperative social structures, nest-building, and collective problem-solving.

Autocatalytic networks, in which the populations are of simulated enzymes and the interactions are equivalent to catalysis. Such networks are capable of self-generation and a growth in complexity, mimicking the bootstrapping process that presumably gave rise to life on Earth.

Current Status

Like most new fields, AL has undergone cycles of hubris and doubt, innovation and stasis, and differentiation and consolidation. The listing of topics for the latest in the series of workshops started by Langton in 1987 is as broad as ever, although probably the bulk of AL work today (2004) is focused on artificial evolution. Most research concentrates on fine details, while the basic philosophical questions remain largely unanswered. Nevertheless, AL remains one of relatively few fields where one can ask direct questions about one's own existence in a practical way.

ATMOSPHERIC AND OCEAN SCIENCES

Earliest works on the study of the atmosphere and ocean date back to Aristotle and his student Theophrastus in 350 BC and further progressed through Torricelli's invention of the barometer in 1643, Boyle's law in 1657, and Celsius's invention of the thermometer in 1742 (due to Galileo in 1607). The first rigorous theoretical model for the study of the atmosphere was proposed by

Vilhelm Bjerknes in 1904, following which many scientists began to apply fundamental physics to the atmosphere and ocean. The advent of these theoretical approaches and the invention of efficient communication technologies in the mid-20th century made numerical weather prediction feasible and was in particular encouraged by Lewis Fry Richardson and John von Neumann in 1946, using the differential equations proposed by Bjerknes. Today, advanced numerical modeling and observational techniques exist, which are constantly being developed further in order to understand and study the complex nonlinear dynamics of the atmosphere and ocean.

This overview article summarizes the governing equations used in atmospheric and ocean sciences, features of atmosphere-ocean interaction, and processes for an idealized geometry and structure with reference to a one-dimensional vertical scale (Figure 1), a two-dimensional vertically averaged scale (Figures 3(a) and 4(a)), a two-dimensional zonally averaged meridional scale (Figures 3(b) and 4(b)), and a three-dimensional scale (Figure 2), and regimes of interacting systems (such as El Niño and Southern Oscillation and North Atlantic Oscillation) (Figures 5–7). The entry serves as an introduction to the many nonlinear processes taking place (for example, chaos, turbulence) and provides a few illustrative examples of self-organizing coherent structures of the nonlinear dynamics of the atmosphere and ocean.

Governing Equations

The combined atmosphere and ocean system can be regarded as a huge volume of fluid resting on a rotating oblate spheroid with varying surface topography moving through space, with an interface (which in general is discontinuous) between two fluid masses of differing densities. This coupled atmosphere-ocean system is driven by energy input through solar radiation (see Figure 1), gravity (for example, through interaction with other stellar bodies such as the Sun and Moon, i.e., tides), and inertia. The entire fluid is described by equations for conserved quantities such as momentum, mass (of air, water vapor, water, salt), and energy together with equations of state for air and water (See **Fluid dynamics; Navier–Stokes equation**). The movement of large water or air masses in a rotating reference frame adds to the complexity of motions, due to the presence of Coriolis forces, introduced by Coriolis in 1835.

Atmosphere-ocean interactions can be defined as an exchange of momentum, heat, and water (vapor and its partial masses: salts, carbon, oxygen, nitrogen, etc.) between air and water masses. The governing equations in the Euler formulation and a cartesian coordinate system are given by:

(i) The conservation of momentum

$$\frac{d\mathbf{u}}{dt} + 2\boldsymbol{\Omega} \times \mathbf{u} = -\frac{1}{\rho}\nabla p - \mathbf{g} + \mathbf{F}_{\text{ext}} + \mathbf{F}_{\text{fric}}, \quad (1)$$

where the second term $2\boldsymbol{\Omega} \times \mathbf{u}$ is the term due to the Coriolis force ($\boldsymbol{\Omega}$ is the angular velocity of the Earth; $|\boldsymbol{\Omega}| = 7.29 \times 10^{-5} \text{ s}^{-1}$), and forces due to a pressure gradient ∇p , gravity ($|\mathbf{g}| = 9.81 \text{ m s}^{-2}$) and external ($\mathbf{F}_{\text{ext}}$) as well as frictional ($\mathbf{F}_{\text{fric}}$) forces are included. Note that the operator d/dt is defined by

$$\frac{d\mathbf{v}}{dt} = \left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) \mathbf{v}.$$

(ii) The conservation of mass (or continuity equation)

$$\frac{1}{\rho} \frac{d\rho}{dt} + \nabla \cdot \mathbf{u} = 0. \quad (2)$$

Note that there are alternative formulations such as the Lagrangian and impulse-flux form for these equations, and cartesian coordinate systems can be mapped to different geometries such as spherical coordinates by appropriate transformations.

(iii) The conservation of energy (First Law of Thermodynamics) and Gibbs's equation (Second Law of Thermodynamics)

$$\begin{aligned} \frac{dQ}{dt} &= \frac{d\varepsilon}{dt} + p \frac{d\alpha}{dt}, \\ \frac{d\eta}{dt} &= \frac{1}{T} \frac{d\varepsilon}{dt} + \frac{p}{T} \frac{d\alpha}{dt} - \sum \frac{\mu_i}{T} \frac{d\gamma_i}{dt}, \end{aligned} \quad (3)$$

where Q is the heat supply (sensible, latent, and radiative heat fluxes; see Figure 1), T is the temperature, ε the internal energy and α the specific volume ($\alpha = 1/\rho$), η the entropy, μ_i the chemical potentials, and γ_i the partial masses. The conservation of energy states in brief that the change in heat is balanced by a change in internal energy and mechanical work performed, and Gibbs's equation determines the direction of an irreversible process, relating entropy to a change in internal energy, volume, and partial masses.

(iv) The conservation of partial masses of water and air, that is, salinity for water, where all constituents are represented as salts and water vapor for air, yield equations similar to (2)

$$\frac{1}{\rho_v} \frac{d\rho_v}{dt} + \nabla \cdot \mathbf{u} = W_v$$

and

$$\frac{d\rho_s}{dt} + \rho_s \nabla \cdot \mathbf{u} = W_s, \quad (4)$$

where ρ_v is the density of water vapor, s the specific salinity (gram salts per gram water), and W_v, W_s

Figure 1. Sketch of the vertical structure of the atmosphere-ocean system and radiation balance and processes in the global climate system. Adapted from National Academy of Sciences (1975). Note that lengths are not to scale and temperatures indicate only global averages.

contain possible source and sink terms as well as the effect of molecular diffusion in terms of the concentration flux density $\mathbf{S}(-\nabla \cdot \mathbf{S})$ and possible phase changes.

(v) The equation of state for a mixture of salts and gases for air and water, whose constituent concentrations are virtually constant in the atmosphere and ocean is

$$p \approx \rho RT (1 + 0.6078 q), \quad (5)$$

where R is the gas constant for dry air ($R = 287.04 \text{ J kg}^{-1} \text{ K}^{-1}$) and $q = \rho_v / \rho$ is the specific humidity. Similarly, the equation of state for near incompressible water is

$$\rho \approx \rho_0 [1 - \alpha(T - T_0) + \beta(S - S_0)], \quad (6)$$

where ρ_0 , T_0 , and S_0 are reference values for density, temperature, and salinity ($\rho_0 = 1028 \text{ kg m}^{-3}$, $T_0 = 283 \text{ K} (= 10^\circ\text{C})$, $S_0 = 35\text{‰}$), and α and β are the coefficients of thermal expansion and saline contraction ($\alpha = 1.7 \times 10^{-4} \text{ K}^{-1}$, $\beta = 7.6 \times 10^{-4}$), see Krauss (1973); Cushman-Roisin (1993).

Equations detailed in (i)–(v) form a set of hydrothermodynamic equations for the atmosphere-ocean system to which various approximations and scaling limits can be applied. Among them are the shallow-water equations, primitive equations, the Boussinesq and anelastic approximation, quasigeostrophic, and semi-geostrophic equations and variants or mixtures of these. These equations have to be solved with appropriate boundary conditions and conditions at the air-sea interface; for details refer to Krauss (1973), Gill (1982) and Kraus & Businger (1994). For studies of the up-

per atmosphere, further equations for the geomagnetic field can also be taken into account (Maxwell's equations).

Atmospheric Structure and Circulation

In the vertical dimension, several atmospheric layers can be differentiated (see Figure 1). Figure 2 gives the length and time scales of typical atmospheric processes.

From sea level up to about 2 km is the atmospheric boundary layer, characterized by momentum, heat, moisture, and water transfer between the atmosphere and its underlying surface. Above the boundary layer is the troposphere (Greek, *tropos* meaning *turn, change*) that constitutes most of the total mass of the atmosphere (about 10 km height) and is largely in hydrostatic balance characterized by a decrease in temperature. Above the troposphere and stratosphere, which contains the ozone layer, temperatures rise throughout. The mesosphere, which is bounded by the stratopause (about 50 km height) below and mesopause (about 85 km height) above, is a layer of very thin air where temperatures drop to extreme lows. Above the mesopause, temperatures increase again throughout the thermosphere (from about 85 km to 700 km), the largest layer of the atmosphere, where the ionosphere is located (between about 100 km and 300 km). The ionosphere contains ionized atoms and free electrons and permits the reflection of electromagnetic waves. Above the thermosphere is the exosphere, which is the outermost layer of the atmosphere and the transition region between the atmosphere and outer space, the magnetosphere in particular, where atoms can escape into space beyond the so-called escape velocity and where the Van Allen belt is situated.

Figure 2. Schematic logarithmic time and horizontal length scales of typical atmospheric and oceanic phenomena. Note that Richardson's $L \propto T^{3/2}$ relation and CE stands for circumference of the Earth. Modified from Lettau (1952), Smagorinsky (1974), and World Meteorological Organization (1975).

A low (high) in meteorology refers to a system of low (high) pressure, a closed area of minimum (maximum) atmospheric pressure (closed isobars, or contours of constant pressure) on a constant height chart. A low (high) is always associated with (anti)cyclonic circulation, thus also called a cyclone (anticyclone). Anticyclonic means clockwise in the Northern Hemisphere (and counterclockwise in the Southern Hemisphere). Cyclonic means counterclockwise in the Northern Hemisphere (and clockwise in the Southern Hemisphere). At zeroth order, a balance of pressure gradient forces and Coriolis forces, that is, geostrophic balance, occurs, leading to the flow of air along isobars instead of across (in the direction of the pressure gradient). A front is a discontinuous interface or a region of strong gradients between two air masses of differing densities or temperatures, thus encouraging conversion of poten-

Figure 3. Sketch of the near-surface climate and atmospheric circulation of the Earth with an idealized continent. (a) Averaged isothermals of the coldest month (dashed-dot, -3°C , 18°C) and the warmest month (solid, 0°C , 10°C) and periodical dry season boundaries α and dry climate β . The following climate regions are indicated: wet equatorial climate (Af), tropical wet/dry climate (Aw), desert climate (BW), steppe climate (BS), sinic climate (Cw), Mediterranean climate (Cs), humid subtropical climate (Cf), humid continental climate (Df), continental subarctic climate (Dw), tundra climate (ET) and snow and ice climate (EF). Modified from Köppen (1923). (b) The zonal mean jet streams (primary circulation) and mass overturning (secondary circulation) in a meridional height section, the subtropical highs (H) and subpolar lows (L), polar easterlies, westerlies, polar front, trade winds, and intertropical convergence zone (ITCZ). $\blacktriangle$ denotes a cold front and $\blacktriangle$ a warm front. Adapted from Palmen (1951), Defant and Defant (1958), and Hantel in Bergmann & Schäfer (2001).

tial into kinetic energy (examples are polar front, arctic front, cold front, and warm front).

Hurricanes and typhoons (local names for tropical cyclones) transport large amounts of heat from low to mid and high latitudes and develop over oceans. Little is known about the initial stages of their formation, although they are triggered by small low-pressure systems in the Intertropical Convergence Zone (*See Hurricanes and tornadoes*). Because of their strong winds, cyclones are particularly active in inducing

Figure 4. Sketch of the oceanic circulation of an idealized basin (a) the global wind-induced distribution of ocean currents (primary circulation) and (b) the zonal mean thermohaline circulation (secondary circulation) in a meridional depth section showing upper, intermediate, deep and bottom water masses. NE denotes the north equatorial, EC the equatorial and SE the south equatorial current. upwelling and wind-driven surface water transport. Extratropical cyclones are frontal cyclones of mid to high latitudes (see Figures 2 and 3).

Meteorology and oceanography are concerned with understanding, predicting, and modeling the weather, climate, and oceans due to their fundamental socio-economic and environmental impact. In meteorology, one distinguishes between short (1–3 days) and medium-range (4–10 days) numerical weather prediction models (NWP) for the atmosphere and general circulation models (GCMs, *See General circulation models of the atmosphere*). While NWP for local and regional weather prediction are usually not coupled to ocean models, GCMs are global three-dimensional complex coupled atmosphere-ocean models (which even include the influence of land masses), used to study global climate change, modeling radiation, photochemistry, transfer of heat, water vapor, momentum,

greenhouse gases, clouds, ocean temperatures, and ice boundaries. The atmosphere-ocean interface couples the “fast” processes of the atmosphere with the comparably “slow” processes of the ocean through evaporation, precipitation, and momentum interaction. GCMs are validated using statistical techniques and correlated to the actual climate evolution. Additionally, the application of GCMs to different planetary atmospheres, for example, on Mars and Jupiter, leads to a greater understanding of the planet’s history and environment.

The complexity of the dynamics of the atmosphere and ocean is largely due to the intrinsic coupling between these two large masses at the air-sea interface.

Ocean

Ocean circulation is forced by tidal forces (also known to force atmospheric tides), due to gravitational attraction, wind stress, applied shear forces acting on the interface, and external, mainly solar, radiation, penetrating into the sea surface and affecting the heat budget and water mass due to evaporation. Primary sources of tidal forcing, earliest work on which was undertaken by Pierre-Simon Laplace in 1778, are the Moon and the Sun. One discerns between diurnal, semidiurnal, and mixed-type tides.

In the ocean, one distinguishes between two types of ocean currents: surface (wind-driven) and deep circulation (thermohaline circulation). Separating the surface and deep circulation is the thermocline, a small layer of strong gradient of temperature, salinity, and density, acting as an interface between the two types of circulations.

Surface circulation ranging up to 400 m in depth is forced by the prominent westerly winds in the mid-latitudes and trade winds in the tropical regions (see Figures 3 and 4), which are both forced by solar heating and Coriolis forces leading to expansion of water near the equator and decreased density, but increased salinity due to evaporation. An example of the latter is the Gulf Stream in the North Atlantic. The surface wind stress, solar heating, Coriolis forces, and gravity lead to the creation of large gyres in all ocean basins with clockwise (anticyclonic) circulation in the northern hemisphere and counterclockwise circulation in the southern hemisphere. The North Atlantic Gyre, for example, consists of four currents: the north equatorial current, the Gulf Stream, the North Atlantic current, and the Canary current.

Ekman transport, the combination of wind stress and Coriolis forces, leads to a convergence of water masses in the center of such gyres, which increases the sea surface elevation. The layer of Ekman transport can be 100–150 m in depth and also leads to upwelling due to conservation of mass on the western (eastern) coasts for winds from the north (south) in the Northern (Southern) Hemisphere. As a consequence, nutrient-rich

Figure 5. Sketch of the global conveyor belt through all oceans, showing the cold saline deep circulation, the warm, less salty surface circulation, and the primary regions of their creation. Note that this circulation is only characteristic of the actual global circulation. Adapted from Broecker (1987).

deep water is brought to the surface. With the opposite wind direction, Ekman transport acts to induce downwelling.

Another important combination of forces is the balance of Coriolis forces and gravity (pressure gradient forces), which is called geostrophic balance, leading to the movement of mass along isobars instead of across (geostrophic current), similar to the atmosphere. The boundary currents along the eastern and western coastlines are the major geostrophic currents in a gyre. The western side of the gyre is stronger than the eastern due to the Earth's rotation, called western intensification.

Deep circulation makes up 90% of the total water mass and is driven by density forces and gravity, which in turn is a function of temperature and salinity. High-density deep water originates in the case of extreme cooling of the sea surface in the polar regions, sinking to large depths as a density current, a strongly nonlinear phenomenon. When the warm Gulf Stream waters, which have increased salinity due to excessive evaporation in the tropics, move north due to the North Atlantic Gyre, they are cooled by Arctic winds from the north and sink to great depths forming the high-density Atlantic deep waters (see Figure 5). The downward trans-

port of water is balanced by upward transport in low- and mid-latitude regions.

The most prominent example of the interaction between atmospheric and ocean dynamics is the global conveyor belt, which links the surface (wind-driven) and deep (thermohaline) circulation to the atmospheric circulation. The global conveyor belt is a global circulatory system of distinguishable and recognizable water masses traversing all oceans (see Figure 5). The water masses of this global conveyor belt transport heat and moisture, contributing to the climate globally. In Earth's history, the global conveyor belt has experienced flow reversals and perturbations leading to changes in the global circulatory system. The rather recent anthropogenic impact on climate and oceans through greenhouse gas emissions has the potential to create instability in this large-scale dynamical system, which could alter Earth's climate and have devastating environmental and agricultural effects.

ENSO and NAO

Another example of atmosphere-ocean coupling is the combination of the El Niño and Southern Oscillation (ENSO). The El Niño ocean current (and associated

Figure 6. Sketch of the El Niño in the tropical Pacific, showing a reversal in (trade) wind direction from easterlies to westerlies during an El Niño period bringing warmer water (warm corresponds to a positive sea-surface temperature [SST]) close to the South American coast, displacing the equatorial thermocline downwards. Note the change in atmospheric tropical convection and associated heavy rainfall. After McPhaden, NOAA/TAO (2002) and Holton (1992).

wind and rain change) is named from the Spanish for Christ Child, due to its annual occurrence off the South American coast around Christmas, and may also be sensitive to anthropogenic influence (see Figure 6). The Southern Oscillation occurs as a 2–5-year periodic reversal in the east–west pressure gradient associated with the present equatorial wind circulation, called Walker circulation, across the Pacific leading to a reversal in wind direction and changes in temperature and precipitation. The easterly wind in the West Pacific becomes a westerly. As a consequence, the strong trade winds are weakened, affecting climate globally (e.g., crop failures in Australia, flooding in the USA, and the monsoon in India). The Southern Oscillation in turn leads to large-scale oceanic fluctuations in the circulation of the Pacific Ocean and sea-surface tempera-

Figure 7. Sketch of the North Atlantic Oscillation (NAO) during the northern hemisphere winter season. Positive NAO (NAO+) shows an above-usual strong subtropical high-pressure center and subpolar low, resulting in increased wind strengths and storms crossing the Atlantic towards northern Europe. NAO+ is associated with a warm wet winter in Europe and cold dry winter in North America. Central America experiences mild wet winter conditions. Negative NAO (NAO–) shows a weaker subtropical high and subpolar low, resulting in lower wind speeds and weaker storms crossing the Atlantic toward southern Europe and receded sea ice masses around Greenland. NAO– is associated with cold weather in northern Europe and moist air in the Mediterranean. Central America experiences colder climates and more snow. Adapted from Wanner (2000).

tures, which is called El Niño. The interannual variability, though, is not yet fully understood; consideration of a wider range of tropical and extratropical influences is needed. A counterpart to the ENSO in the Pacific is the North Atlantic Oscillation (NAO), which is essentially an oscillation in the pressure difference across the North Atlantic and is described further in Figure 7.

Monsoons

The monsoons (derived from Arabic, *mausim*, meaning season or shift in wind) are seasonally reversing

winds and one of the most pertinent features of the global atmospheric circulation. The best-known examples are the monsoons over the Indian Ocean and, to some extent, the western Pacific Ocean (tropical region of Australia), the western coast of Africa, and the Caribbean. Monsoons are characteristic for wet summer and dry winter seasons, associated with strong winds and cyclone formation. They occur due to differing thermal characteristics of the land and sea surfaces. Land, having a much smaller heat capacity than the ocean, emits heat from solar radiation more easily, leading to upward heat (cumulus) convection. In the summer season, this leads to a pressure gradient and thus wind from the land to the ocean in the upper layers of the atmosphere and subsequent conserving flow of moisture-rich air from the sea back inland at lower levels. This leads to monsoonal rains, increased latent heat release, and intensified monsoon circulation. During the monsoons of the winter season, the opposite of the summer season monsoon takes place, although less pronounced, since the thermal gradient between the land and sea is reversed. The winter monsoons thus lead to precipitation over the sea and cool dry land surfaces.

ATTRACTOR NEURAL NETWORKS

Neural networks with feedback can have complex dynamics; their outputs are not related in a simple way to their inputs. Nevertheless, they can perform computations by converging to attractors of their dynamics. Here, we analyze how this is done for a simple example problem: associative memory, following the treatment by Hopfield (1984) (see also Hertz, et al., 1991, Chapters 2 and 3).

Let us assume that input data are fed into the network by setting the initial values of the units that make it up (or a subset of them). The network dynamics then lead to successive changes in these values. Eventually, the network will settle down into an attractor, after which the values of the units (or some subset of them) give the output of the computation. The associative memory problem can be described in the following way: there is a set of p patterns to be stored. Given, as input, a pattern that is a corrupted version of one of these, the attractor should be a fixed point as close as possible to the corresponding uncorrupted pattern.

We focus on networks described by systems of differential equations such as

$$\tau_i \frac{du_i}{dt} + u_i(t) = \sum_{j \neq i} w_{ij} g[u_j(t)]. \quad (1)$$

Here, $u_i(t)$ is the net input to unit i at time t and $g(\cdot)$ is a sigmoidal activation function ($g' > 0$), so that $V_i = g(u_i)$ is the value (output) of unit i . The connection weight to unit i from unit j is denoted w_{ij} , and τ_i is the relaxation time. We can also consider discrete-time systems governed by

$$V_i(t+1) = g \left[\sum_j w_{ij} V_j(t) \right]. \quad (2)$$

Here, it is understood that all units are updated simultaneously. In either case, the “program” of such a network is its connection weights w_{ij} .

In general, three kinds of attractors are possible: fixed point, limit cycle, and strange attractor. There are conditions under which the attractors will always be fixed points. For nets described by the continuous dynamics of Equation (1), a sufficient (but not necessary) condition is that the connection weights be symmetric: $w_{ij} = w_{ji}$. General results about the stability of recurrent nets were proved by Cohen & Grossberg (1983). They showed, for dynamics (1), that there is a Lyapunov function, that is, a function of the state variables u_i , which always decreases under the dynamics, except for special values of the u_i at which it does not change. These values are fixed points. For values of the u_i close to such a point, the system will evolve either toward it (an attractor) or away

from it (a repeller). For almost all starting states, the dynamics will end at one of the attractor's fixed points. Furthermore, these are the only attractors.

We treat the case $g(u) = \tanh(\beta u)$ and consider the *ansatz*

$$w_{ij} = \frac{1}{N} \sum_{\mu=1}^p \xi_i^{\mu} \xi_j^{\mu}. \quad (3)$$

That is, for each pattern, there is a contribution to the connection weight proportional to the product of sending (ξ_j^{μ}) and receiving (ξ_i^{μ}) unit activities when the network is in a stationary state $V_i = \xi_i^{\mu}$. This is just the form of synaptic strength proposed by Hebb (1949) as the basis of animal memory, so this *ansatz* is sometimes called a Hebbian storage prescription.

To see how well the network performs this computation, we examine the fixed points of (1) or (2), which solve

$$V_i = \tanh \left(\beta \sum_j w_{ij} V_j \right). \quad (4)$$

The quality of retrieval of a particular stored pattern ξ_i^{μ} is measured by the quantity $m_{\mu} = N^{-1} \sum_i \xi_i^{\mu} V_i$. Using (4), with the weight formula (3), we look for solutions in which the configuration of the network is correlated with only one of the stored patterns, that is, just one of the m_{μ} 's is not zero. If the number of stored patterns $p \ll N$, we find a simple equation for m_{μ} :

$$m_{\mu} = \tanh(\beta m_{\mu}). \quad (5)$$

This equation has nontrivial solutions whenever the gain $\beta > 1$ and for β large, $m_{\mu} \rightarrow 1$, indicating perfect retrieval. If the gain is high enough, there are other attractors in addition to the ones we have tried to program into the network with the choice (3), but by keeping the gain between 1 and 2.17 we can limit the attractor set to the desired states.

When p is of the same order as N , the analysis is more involved. We define a parameter $\alpha = p/N$. For small α , the overlaps m_{μ} between the stored patterns and the fixed points are less than, but still close to, 1. However, there is a critical value of α , $\alpha_c(\beta)$, above which there are no longer fixed points close to the patterns to be stored and the memory breaks down catastrophically. One finds $\alpha_c(1) = 0$ and, in the limit $\beta \rightarrow \infty$, $\alpha_c(\beta) \rightarrow 0.14$.

Thus, attractor computation works in this system over a wide range of the model parameters α and β . It can be shown to be robust with respect to many other variations, including dilution (random removal of connections), asymmetry (making some of the $w_{ij} \neq w_{ji}$),

and quantization or clipping of the weight values. Its breakdown at the boundary $\alpha_c(\beta)$ is a collective effect like a phase transition in a physical system.

The weight formula (3) was only an educated guess. It is possible to obtain better weights, which reduce the crosstalk and increase α_c , by employing systematic learning algorithms.

It is also possible to extend the above-described model to store pattern sequences by including suitable delays in the discrete-time dynamics (2).

It appears that attractor networks play a role in computations in the brain. One example of current interest is working memory: some neurons in the prefrontal cortex that are selectively sensitive to a particular visual stimulus exhibit continuing activity after the stimulus is turned off, even though the animal sees other stimuli. Thus, they seem to be involved in the temporary storage of visual patterns. Computational network models based on the simple concepts described above (Renart et al., 2001) are able to reproduce the main features seen in recordings from these neurons.

ATTRACTORS

A wide variety of problems arising in physics, chemistry, and biology can be recast within the framework of dynamical systems. A dynamical system is made up of two parts: the phase space, which consists of all possible configurations of the physical system, and the “dynamics,” a rule describing how the state of the system changes over time. The fundamental insight of the theory is that some problems, which initially appear extremely complicated, can be greatly simplified if we are prepared to concentrate on their long-term behavior, that is, what happens eventually.

This idea finds mathematical expression in the concept of an attractor.

The simplest possibility is that the system settles down to a constant state (e.g., a pendulum damped by air resistance will end up hanging vertically downward). In the phase space, this corresponds to an attractor that is a single “fixed point” for the dynamics. If the system settles down to a repeated oscillation, then this corresponds to a “periodic orbit,” a closed curve in the phase space. For two coupled ordinary differential equations (ODEs), it is a consequence of the Poincaré–Bendixson Theorem that these fixed points and periodic orbits are essentially the only two kinds of attractors that are possible (see Hirsch & Smale, 1974 for a more exact statement). In higher dimensions, it is possible for the limiting behavior to be quasi-periodic with k different frequencies, corresponding to a k -torus in the phase space (cf. Landau’s picture of turbulence as in Landau & Lifschitz, 1987).

However, with three or more coupled ODEs (or in one-dimensional maps), the attractor can be an extremely complicated object. The famous “Lorenz attractor” was perhaps the first explicit example of an attractor that is not just a fixed point or (quasi) periodic orbit. Edward Lorenz highlighted this in the title of his 1963 paper, “Deterministic Nonperiodic Flow.” The phrase “strange attractor” was coined by Ruelle & Takens (1971) for such complicated attracting sets. These attractors, and the chaotic dynamics associated with them, have been the focus of much attention, particularly in relation with the theory of turbulence (the subject of Ruelle & Takens’ paper; see also Ruelle, 1989). There is no fixed definition of a “strange attractor”; some authors use the phrase as a signature of chaotic dynamics, while others use it to denote a fractal attractor (e.g., Grebogi et al. (1984) discuss “strange nonchaotic attractors”).

Over the years, various authors have given precise (but different) definitions of an attractor: Milnor (1985) discusses many of these (and proposes a new one of his own). Most definitions require that an attractor attract a “large set of initial conditions and satisfy some kind of minimality property” (without this, the whole phase space could be called an attractor).

We refer to the set of all those points in the phase space whose trajectories are attracted to some set A as the basin of attraction of A and write this $B(A)$. There are essentially two choices of what it means to attract a large set of initial conditions: the more common one is that $B(A)$ contains an open neighborhood of A , while Milnor (1985) suggested that a more realistic requirement is that $B(A)$ has positive Lebesgue measure.

Exactly what type of minimality assumption we require depends on what we want our attractor to say about the dynamics. At the very least, there should be no smaller (closed) set with the same basin of

Figure 1. (a) A symmetric double-well potential. (b) Phase portrait of a particle moving in the potential of (a) with friction.

attraction: this excludes any “unnecessary” points from the attractor. A consequence of this minimality property is that the attractor is invariant: if A is the attractor of a map f , this means that $f(A) = A$ (there is, of course, a similar property for the attractor of a flow). In particular, this means that it is possible to talk about the “dynamics on the attractor.”

If we want one attractor to describe the possible asymptotic dynamics of *every* initial condition, then there is no need to impose any further minimality assumption. Figure 1(b) shows the phase portrait for a particle moving with friction in the symmetric double-well potential of Figure 1(a); the basin of attraction of the fixed point corresponding to the bottom of the left-hand well is shaded. (The equations of motion are $\dot{x} = y$ and $\dot{y} = -\frac{y}{2} + x - x^3$.) We could say that the attractor consists of the three points $\{(-1, 0), (1, 0), (0, 0)\}$, but this discards much of the information contained in the phase portrait. This motivates the further requirement that an attractor be “indecomposable”: it should not be possible to split it into two disjoint invariant subsets. (Some definitions require there to be a dense orbit in

the attractor: essentially, this means that one trajectory “covers” the entire attractor, so in particular the attractor cannot be split into two pieces.) This gives us two possible attractors: $(-1, 0)$ and $(1, 0)$ (the origin does not attract a neighborhood of itself, nor any set of positive measure).

In this example, the boundary between the basins of attraction of the two competing attractors is a smooth curve. However, in many examples this boundary is a fractal set. This was first noticed by McDonald et al. (1985), who observed that near a fractal boundary, it is harder to predict the asymptotic behavior of imprecisely known initial conditions. An extreme version of this occurs with the phenomenon of “riddled basins,” first observed by Alexander et al. (1992): arbitrarily close to a point attracted to one attractor; there can be a point attracted to another. In this case, an arbitrarily small change in the initial condition can lead to completely different asymptotic behavior. (In addition to treating some analytically tractable examples, Alexander et al. (1992) give an impressive array of pictures from their numerical simulations.)

Attractors can also be meaningfully defined for the infinite-dimensional dynamical systems arising from partial and functional differential equations (e.g., Hale, 1988; Robinson, 2001; Temam 1988/1996), and for random and nonautonomous systems (Crauel et al. (1997) adopt an approach that includes both these cases).

AUBRY-MATHER THEORY

Named after Serge Aubry and John Mather, who independently shaped the seminal ideas, the Aubry–Mather theory addresses one of the central problems of modern dynamics: the characterization, of nonintegrable Hamiltonian time evolution beyond the realm of perturbation theory. In general terms, when a Hamiltonian system is near-integrable, perturbation theory provides a rigorous generic description of the invariant sets of motion (closed sets containing trajectories) as smooth surfaces (KAM tori), each one parametrized by the rotation number ω of the angle variable (angle-action coordinates): all the trajectories born and living inside the invariant torus share this common value of ω . An invariant set has an associated natural invariant measure, which describes the measure-theoretical (or statistical) properties of the trajectories inside the invariant set. The invariant measure on a torus is a continuous measure, so that the distribution function of the angle variable is continuous. In this near-integrable regime of the dynamics, perturbative schemes converge adequately and future evolution is—to a desired arbitrary degree—predictable for arbitrary initial conditions on each torus.

Far from integrable Hamiltonian dynamics, what is the fate of these invariant natural measures, or invariant sets of motion, beyond the borders of validity of perturbation theory? The answer is that each torus breaks down and its remaining pieces form an invariant fractal set, called by Percival a cantorus (or Aubry–Mather set) characterized by the rotation number value common to all trajectories in the cantorus. The statistical properties of the trajectories on the invariant cantorus are now described by a purely discrete measure or Cantor distribution function (see Figure 1).

Basic Theorems

The formal setting of Aubry–Mather theory for the transition from regular motion on invariant tori to orbits on hierarchically structured nowhere dense cantori is the class of maps of a cylindrical surface $\mathcal{C} = \mathbb{S}^1 \times \mathcal{R}$ (cylindrical coordinates (u, p)) (see Figure 2) onto itself,

$$f : \mathcal{C} \rightarrow \mathcal{C}, \quad (1)$$

characterized by preservation of areas (symplectic) and the “twist” property, meaning that the torsion produced by an iteration of the map on a vertical segment of the cylindrical surface converts it into a part of the graph

Figure 1. Left: Construction of a Cantor set from the unit real interval (or circle S^1) as a limiting process. At each step n , a whole piece is cut out from each remaining full segment. Right: The distribution function $F(u)$ of the projection onto the angular component u_n of a cantorus orbit. $F(u)$ is the limiting proportion of the values of $u_n < u$, $-\infty < n < +\infty$.

Figure 2. Schematic illustration on the unfolded cylindrical surface $\mathcal{C} = S^1 \times \mathcal{R}$ of the twist (upper right) and area-preserving (lower right) properties of the map $F : \mathcal{C} \rightarrow \mathcal{C}$. In the upper right area the curve is a single-valued function $\varphi(u)$ of the angular variable.

of some function $\varphi(u)$ of the angular coordinate. More explicitly, if we denote by $(u', p') = f(u=0, p)$ the image of the vertical segment, then u' is a monotone function of p , so that (u', p') is the graph of a single-valued function.

An area-preserving twist map has associated an action-generating function related to the map via a variational (extremal action) principle:

- An action-generating function, $H(x, x')$, of a twist map is a two-variable function that is strictly convex:

$$\frac{\partial^2 H}{\partial u \partial u'} \leq K < 0. \quad (2)$$

- If u_0 is a critical point of $\mathcal{L}(x) = H(u_{-1}, x) + H(x, u_1)$, then a certain sequence (u_{-1}, p_{-1}) , (u_0, p_0) , (u_1, p_1) is a segment of a cylinder orbit of f .

Given a sequence $\{u_j\}_{j=0}^n$ with fixed ends ($u_0 = a$, $u_n = b$), the associated action functional $\mathcal{L}$ is the sum $\sum_{j=0}^{n-1} H(u_j, u_{j+1})$.

A cylinder orbit is called ordered when it projects onto an angular sequence ordered in the same way as a uniform rotation of angle ω . An invariant set is a minimal invariant set if it does not include proper invariant subsets and is called ordered if it contains only ordered orbits. The proper definition of an Aubry–Mather set is a minimal invariant ordered set that projects one-to-one on a nowhere dense Cantor set of the circle S^1 .

The following points comprise the main core (Golé, 2001; Katok & Hasselblatt, 1995) of the Aubry–Mather theory:

- For each rational value $\omega = p/q$ of the rotation number, there exist (Poincaré–Birkhoff theorem) at least two ordered periodic orbits (Birkhoff periodic orbits of type (p, q)), which are obtained by, respectively, minimizing and maximizing the action over the appropriate set of angular sequences.
- In general, periodic orbits of rational rotation number $\omega = p/q$ do not form an invariant circle, in which case there are nonperiodic orbits approaching two different periodic orbits as $n \rightarrow -\infty$ and as $n \rightarrow +\infty$, called heteroclinic orbits (or homoclinic in some contexts). These orbits connect two Birkhoff periodic orbits through a minimal action path. Usually, the number of map iterations needed for such action-minimizing orbits to pass over the action barriers is exponentially small.
- For each irrational value of ω , there exists either an invariant torus or an Aubry–Mather set. There are also homoclinic trajectories connecting orbits on the Aubry–Mather set.

The hierarchical structure of gaps that break up the torus has its origins in the path-dependent action barriers. Note also that heteroclinics to nearby periodic orbits (of rational rotation number) pass over nearly the same action barriers, leading to a

somewhat metaphorical view of nearby resonances biting the tori and leaving gaps. Certainly, the action barriers fractalize the invariant measure according to the proximity of the irrational rotation number ω to rationals.

The explanatory power of the extremal action principle in the fractalization of invariant sets of motion suggests one of the immediate physical applications of this theory. Indeed, Aubry's work was originally motivated by the equilibrium problem of a discrete field (u_n) $n \in \mathbb{Z}$, under some energy functional, whose extremalization defines equilibrium field configurations. Under some conditions on the energy-generating function $H(u, u')$, both are equivalent mathematical physics problems, and a one-to-one correspondence between orbits (u_n, p_n) and equilibrium field configurations (u_n) does exist (Aubry, 1985).

Application to the Generalized Frenkel-Kontorova Model

From this perspective, the Aubry-Mather theory gives rigorous variational answers in the description of equilibrium discrete nonlinear fields such as the generalized Frenkel-Kontorova (FK) model with convex interactions. Although the terminology changes, every aspect of cylinder dynamics has a counterpart in the equilibrium problem of this interacting nonlinear many-body model.

- Commensurate (periodic) field configurations correspond to Birkhoff periodic orbits, and as such they are connected by the field configurations associated to heteroclinics, which are here called discrete (sine-Gordon) solitons or elementary discommensurations.
- Incommensurate (quasiperiodic) field configurations can correspond either to tori trajectories or to Aubry-Mather trajectories. The macroscopic physical properties (formally represented by averages on the invariant measure) of the field configuration experience drastic changes when passing from one case (tori) to the other (Aubry-Mather sets). This transition (called breaking of analyticity by Aubry) has been characterized as a critical phenomenon using renormalization group methods by (MacKay, 1993).

The Aubry-Mather theory puts on a firm basis what is known as discommensuration theory, which is the description of a generic incommensurate or (higher-order) commensurate field configuration as an array of discrete field solitons, strongly interacting when tori subsist, but almost noninteracting and deeply pinned when only Cantor invariant measures remain. Aubry's work provided a satisfactory understanding of the complexity of the phase diagrams and the singular character of the equations of state of the generalized FK model (Griffiths, 1990).

AVALANCHE BREAKDOWN

Charge transport in condensed matter is simply described by the current density j as a function of the local electric field E . For bulk materials, the current density per unit area is given by $j(E) = -env$, where $e > 0$ is the electron charge, n is the conduction electron density per unit volume, and v is the drift velocity. In the simplest case, v is a linear function of the field: $v = -\mu E$, with mobility μ .

Thus, the conductivity $\sigma = j/E = en\mu$ is proportional to the number of conduction electrons. In metals, n is given by the number of valence electrons, which is temperature independent. In semiconductors, however, the concentration of electrons in the conduction

band varies greatly and is determined by generation-recombination (GR) processes that induce transitions between valence band, conduction band, and impurity levels (donors and acceptors). Charge carrier concentration depends not only upon temperature but also upon the electric field, which explains why the conductivity can change over many orders of magnitude. A GR process that depends particularly strongly on the field is impact ionization, the inverse of the Auger effect. It is a process in which a charge carrier with high kinetic energy collides with a second charge carrier, transferring its kinetic energy to the latter, which is thereby lifted to a higher energy level. The kinetic energy is increased by the local electric field, which heats up the carriers. As a certain minimum energy is necessary to overcome the difference in the energy levels of the second carrier, the impact ionization probability depends in a threshold-like manner on the applied voltage.

Impact ionization processes may be classified as band-band processes or band-trap processes depending on whether the second carrier is initially in the valence band and makes a transition from the valence band to the conduction band, or whether it is initially at a localized level (impurity, donor, acceptor), and makes a transition to a band state. Further, impact ionization processes are classified as electron or hole processes according to whether the ionizing hot carrier is a conduction band electron or a hole in the valence band.

Schematically, impact ionization may be written as one of the following reaction equations, in analogy with chemical kinetics:

where e and h denote band electrons and holes, respectively, and e_t and h_t stand for electrons and holes trapped at impurities (donors, acceptors, or deep levels). The result of the process is carrier multiplication (avalanching), which may induce electrical instabilities at sufficiently high electric fields. Impact ionization from shallow donors or acceptors is responsible for impurity breakdown at low temperatures. Being an autocatalytic process (i.e., each carrier ionizes secondary carriers that might, in turn, impact ionize other carriers), it induces a nonequilibrium phase transition between a low- and high-conductivity state and may lead to a variety of spatiotemporal instabilities, including current filamentation, self-sustained oscillations, and chaos. The conductivity saturates when all impurities are ionized. Band-to-band impact ionization eventually induces avalanche breakdown, limiting the bias voltage that can be safely applied to a device. The conductivity increases much more

strongly than during impurity breakdown because of the large number of valence band electrons available for ionization.

Impurity impact-ionization breakdown at helium temperatures (ca. 5 K) in p-Ge, n-GaAs, and other semiconductor materials has been thoroughly studied both experimentally and theoretically as a model system for nonlinear dynamics in semiconductors. It displays S-shaped current-voltage characteristics because the GR kinetics incorporating impact ionization from at least two impurity levels (ground state and excited state) allows for three different values of the carrier density $n(E)$ in a certain range of fields E . As a result of the negative differential conductivity, a variety of temporal and spatiotemporal instabilities occur, ranging from stationary and breathing current filaments and traveling charge density waves to various chaotic scenarios.

Band-to-band impact ionization of a reverse biased p-n junction is the basis of a variety of electronic devices. A number of these devices depend on a combination of impact ionization of hot electrons and transit time effects. The IMPATT (impact ionization avalanche transit time) diodes can generate the highest continuous power output at frequencies > 30 GHz. The originally proposed device (Read diode) involves a reverse biased $n^+ - p - i - p^+$ multilayer structure, where n^+ and p^+ denote strongly n- or p-doped semiconductor regions, and i denotes an intrinsic (undoped) region. In the $n^+ - p$ region (avalanche region), carriers are generated by impact ionization across the bandgap; the generated holes are swept through the i region (drift region) and collected at the p^+ contact. When a periodic (ac) voltage is superimposed on the time-independent (dc) reverse bias, a π phase lag of the ac current behind the voltage can arise. This phase lag is due to the finite buildup time of the avalanche current and the finite time carriers take to cross the drift region (transit-time delay). If the sum of these delay times is approximately one-half cycle of the operating frequency, negative conductance is observed; in other words, the carrier flow drifts opposite to the ac electric field. This can be achieved by properly matching the length of the drift region with the drift velocity and the frequency. Other devices using the avalanche breakdown effect are the TRAPATT (trapped plasma avalanche triggered transit) diode and the avalanche transistor. The Zener diode is a p-n junction that exhibits a sharp increase in the magnitude of the current at a certain reverse voltage where avalanche breakdown sets in. It is used to stabilize and limit the dc voltage in circuits (overload and transient suppressor) since the current can vary over a large range at the avalanche breakdown threshold without a noticeable change in the voltage. The original Zener effect, on the other hand, is due to quantum mechanical tunneling across the bandgap at high fields, and is effective in highly doped (resulting in

narrow depletion layers) Zener diodes at lower breakdown voltages.

AVALANCHES

An avalanche is a downhill slide of a large mass, usually of snow, ice, or rock debris prompted by a small initial disturbance. Avalanches, along with landslides, are one of the major natural disasters that still present significant danger for people in the mountains. On average, 25 people die in avalanches every winter in Switzerland alone. Dozens of people were killed on September 23, 2002, in a gigantic avalanche in Northern Ossetia, Russia, when a 150 m thick chunk of the Kolka Glacier broke off and triggered an avalanche of ice and debris that slid some 25 km along Karmadon gorge. In 1999, some 3000 avalanches occurred in the Swiss Alps.

Avalanches vary widely in size, from minor slides to large movements of snow reaching a volume of 10^5 m^3 and a weight of 30,000 tons. The speed of the downhill snow movement can reach 100 m/s. There are two main types of avalanches—loose avalanche and slab avalanche: depending on the physical properties of snow. Soft dry snow typically produces loose avalanches that form a wedge downward from the starting point, mainly determined by the physical properties of the granular material. In wet or icy conditions, on the other hand, a whole slab of solid dense snow may slide down. The initiation of the second type occurs as a fracture line at the top of the slab. The study of real avalanches and landslides is mostly an empirical science that is traditionally a part of geophysics and draws from the physics of snow, ice, and soil. Semi-empirical computer codes have been developed for prediction of avalanches dependent on the weather conditions (snowfall, wind, temperature profiles) and topography.

Figure 1. Only several layers of mustard seeds are involved in the rolling motion inside the avalanche: moving grains are smeared out in this long-exposure photograph. Reproduced with permission from Jaeger et al. (1998).

More fundamental aspects of avalanche dynamics have been studied in controlled laboratory experiments with dry or wet granular piles, or sandpiles. Granular slope can be characterized by two angles of repose—the static angle of repose θ_s which is the maximum angle at which the granular slope can remain static, and the dynamic angle of repose θ_d , or a minimum angle at which the granular flow down the slope can persist. Typically, in dry granular media, the difference between static and dynamic angles of repose is about $2\text{--}5^\circ$, for smooth glass beads $\theta_s \approx 25^\circ$, $\theta_d \approx 23^\circ$. Avalanches may occur in the bistable regime when the slope angle satisfies $\theta_d < \theta < \theta_s$. The bistability is explained by the need to dilate the granular material for it to enter flowing regime (Bagnold's dilatancy).

An avalanche can be initiated by a small localized fluctuation from which the fluidized region expands downhill and sometimes also uphill, while the sand always slides downhill. An avalanche in a deep sandpile usually involves a narrow layer near the surface (see Figure 1). Avalanches have also been studied in finite-depth granular layers on inclined planes. The two-dimensional structure of a developing avalanche depends on the thickness of the granular layer and the slope angle. For thin layers and small angles, wedge-shaped avalanches are formed similar to the loose snow avalanches (Figure 2a). In thicker layers and at higher inclination angles, avalanches have a balloon-type shape that expands both down- and uphill (Figure 2b).

The kinematics of the fluidized layer in one dimension can be described by a set of hydraulic equations for the local thickness $R(x, t)$ of the layer of rolling particles flowing over a sandpile of immobile particles with variable profile $h(x, t)$ (BCRE model, after Bouchaud et al., (1994)),

$$\partial_t R = -v \partial_x R + \Gamma(R, h) + (\text{diffusive terms}), \quad (1)$$

$$\partial_t h = -\Gamma(R, h) + (\text{diffusive terms}), \quad (2)$$

Figure 2. Structure of the avalanche in a thin (4 grain diameters) layer of glass beads: (a) wedge-shaped avalanche for $\theta = 31.5^\circ$; (b) balloon-shaped avalanche propagating both up- and downhill for $\theta = 32.5^\circ$. where Γ is the entrainment flux of immobile particles into the rolling layer and the downhill transport velocity v is assumed constant. Γ becomes positive when the local slope becomes steeper than the static repose angle θ_s , and in the simplest case, $\Gamma = \gamma R(\partial_x h - \tan \theta_s)$. This model allows for a complete analytical treatment.

A more sophisticated continuum theory of granular avalanches is based on the fluid dynamics (Navier–Stokes) equations coupled with a phenomenological description of the first-order phase transition from a static to a fluidized state driven by the local shear stress (Aranson & Tsimring, 2001). The local phase state is described by the local order parameter ρ that is controlled by a Ginzburg–Landau-type equation with bistable free energy $F(\rho, \delta)$:

$$\partial_t \rho = D \nabla^2 \rho - \partial_\rho F(\rho, \delta) \quad (3)$$

The control parameter δ in this equation depends on the ratio of shear to normal stress. This theory can describe a variety of “partially fluidized” granular flows, including avalanches in sandpiles. In a “shallow-water” approximation, it yields the BCRE-type equations for the local slope and the thickness of the rolling layer.

The wide distribution of scales in real avalanches led Bak et al. (1988) to propose a “sandpile cellular automaton” (See **Sandpile model**) as a paradigm model for *self-organized criticality* (SOC), the phenomenon that occurs in slowly driven nonequilibrium spatially

extended systems when they asymptotically reach a critical state characterized by a power-law distribution of event sizes. The BTW model is remarkably simple, yet it exhibits a highly nontrivial behavior. The sandpile is formed on a lattice by dropping “grains” on a random site from above, one at a time. “Grains” form stacks of integer height at each lattice site. After each grain dropping the sandpile is allowed to relax. Relaxation occurs when the slope (a difference in heights of two adjacent stacks) reaches a critical value (“angle of repose”) and the grain hops to a lower stack. This may prompt a series of subsequent hops and so trigger an avalanche. The size of the avalanche is determined by the number of grains set into motion by adding a single grain to a sandpile. In the asymptotic regime in a large system, the avalanche size distribution becomes scale-invariant, $P(s) \propto s^{-\alpha}$ with $\alpha \approx 1.5$.

The relevance of this model and its generalizations to real avalanches is still a matter of debate. The sandpile model is defined via a single repose angle, and so its asymptotic behavior has the properties of the critical state for a second-order phase transition. Real sandpiles are characterized by two angles of repose and thus exhibit features of the first-order phase transition. Experiments with avalanches in slowly rotating drums do not confirm the scale-invariant distribution of avalanches. However, in such experiments, the internal structures of the sandpile (the force chains) are constantly changing in the process of rotation. In other experiments with large monodispersed glass beads dropped on a conical sandpile, SOC with $\alpha \approx 1.5$ was observed. The characteristics of the size distribution depend on the geometry of the sandpile and the physical and geometrical properties of grains. SOC was also observed in the avalanche statistics in a three-dimensional pile of long rice; however, a smaller scaling exponent $\alpha \approx 1.2$ was measured for the avalanche size distribution.

An avalanche in a pile of sand has been used as a metaphor in many other physical phenomena including the avalanche diodes, vortices in type-II superconductors, Barkhausen effect in ferro-magnetics, $1/f$ noise, and.

AVERAGING METHODS

Averaging methods are generally used for dynamical systems of two or more degrees of freedom when time scales or space scales are well separated. An average over the rapidly varying coordinates of one degree of freedom, considering the coordinates of the second degree of freedom to be constant during the average, can, with appropriate variables, retain a time-invariant quantity that enters into the solution of the slower motion. This solution, in turn, supplies a parameter to the rapid motion, which can then be solved in a lower-dimensional space. The averaging method is closely related to the calculation of *adiabatic invariants*, which are the approximately constant integrals of the motion that are obtained by averaging over the fast angle variables.

The lowest-order calculation is generally straightforwardly performed in canonical coordinates. A transformation from momentum and position coordinates (p, q) , for the fast oscillation, to action-angle form (J, θ) gives a constant of the motion J , if all other variables are held constant. The action J is then the constant parameter in the equation for the slower motion. It is not always convenient to transform to action-angle form directly, but the underlying constants are related to the action variables.

The formal expansion procedure that is employed is to develop the solution in an asymptotic series. The mathematical method applied to ordinary differential equations was developed by Nikolai Bogoliubov (Bogoliubov & Mitropolsky, 1961) and in a somewhat different form by Martin Kruskal (1962). The expansion techniques can be formally extended to all orders in the perturbation parameter but are actually divergent. For multiple periodic systems, higher-order local nonlinear resonances between the degrees of freedom may destroy the ordering in their neighborhood. We will return to this problem below.

Averaging over the fastest oscillation of an N -degree-of-freedom system reduces the number of freedoms to $N - 1$. A second average over the next fastest motion then produces a second adiabatic invariant to reduce the freedoms to $N - 2$. This process may be continued to obtain a hierarchy of adiabatic

Figure 1. A hierarchy of adiabatic invariants for the charged particle gyrating in a nonaxisymmetric, magnetic mirror field. The three adiabatic invariants are the magnetic moment μ , the longitudinal invariant $J_{||}$, and the guiding center flux invariant Φ .

invariants, until the system is reduced to one degree of freedom, which can be integrated to obtain a final integrable equation. The process is well known in plasma physics where, for a charged particle gyrating in a magnetic mirror field, we first find the magnetic moment invariant μ associated with the fast gyration, then find the longitudinal invariant $J_{||}$ associated with the slower bounce motion, and finally find the flux invariant Φ associated with the drift motion. The three degrees of freedom are shown in Figure 1. The small parameters in this case are ϵ_1 , the ratio of bounce frequency to gyration frequency; ϵ_2 , the ratio of guiding center drift frequency to bounce frequency; and ϵ_3 , the ratio of the frequency of the time-varying magnetic field to the drift frequency. This example motivated the development of averaging methods. The derivations of these invariants are given in detail in Northrop (1963) or in other plasma physics texts.

Although the asymptotic expansions are formally good to all orders in a small dimensionless parameter of the form $\epsilon = |\dot{\omega}/\omega^2|$, where ω is the frequency of the fast oscillation that is slowly changing in time and $\dot{\omega} \equiv d\omega/dt$, the series generally diverge. The physical reason is that resonances or near-resonances between degrees of freedom lead to small denominators in the coefficients of terms. For nonlinear coupled oscillatory systems, exact resonances for certain values of the action locally change the structure of the phase-space orbits so that they do not follow the values obtained by averaging. This led to the development of the secular perturbation theory (Born, 1927), in which a local transformation of the coordinates around the resonance can be made. The frequency of the oscillatory motion in the neighborhood of the exact resonance is then slow compared with the other frequencies in the transformed coordinates, and averaging can then be applied locally. A review of the various methods, their limitations, practical examples, and reference to original sources can be found in Lichtenberg (1969) and Lichtenberg & Lieberman (1991).

The above discussion is related to the study of finite-dimensional systems governed by ordinary

differential equations. The methods are usually applied to relatively low-dimensional systems, for example, the motion of a magnetically confined charged particle as described above. However, averaging methods are also applied to systems governed by partial differential equations, such as nonlinear wave propagation problems and wave instabilities. For example, waves on discrete oscillator chains can be obtained by first averaging over the discreteness using a Taylor expansion.

B

BÄCKLUND TRANSFORMATIONS

Bäcklund transformations (BTs) originated in investigations conducted in the late 19th century into invariance properties of pseudospherical surfaces, namely surfaces of constant negative Gaussian curvature. In 1862, it was Edmond Bour who derived the well-known sine-Gordon equation

$$\omega_{uv} = \frac{1}{\rho^2} \sin \omega \quad (1)$$

via the Gauss–Mainardi–Codazzi system for pseudospherical surfaces with total curvature $K = -1/\rho^2$, parametrized in asymptotic coordinates. In 1883, Albert Bäcklund published his now classical result whereby pseudo-spherical surfaces may be generated in an iterative manner. Thus, if $\mathbf{r}$ is the position vector of a pseudospherical surface Σ corresponding to a seed solution ω of Equation (1) and ω' denotes the Bäcklund transformation of ω via the BT

$$\begin{aligned} \omega'_u - \omega_u &= \frac{2\beta}{\rho} \sin\left(\frac{\omega' + \omega}{2}\right), \\ \omega'_v + \omega_v &= \frac{2}{\beta\rho} \sin\left(\frac{\omega' - \omega}{2}\right), \end{aligned} \quad \mathbb{B}_\beta \quad (2)$$

then the position vector $\mathbf{r}'$ of the one-parameter class of surfaces Σ' corresponding to ω' is given by (Bäcklund, 1883)

$$\begin{aligned} \mathbf{r}' &= \mathbf{r} + \frac{L}{\sin \omega} \\ &\times \left[\sin\left(\frac{\omega - \omega'}{2}\right) \mathbf{r}_u + \sin\left(\frac{\omega + \omega'}{2}\right) \mathbf{r}_v \right], \end{aligned} \quad (3)$$

where $L = \rho \sin \zeta$ and $\beta = \tan(\zeta/2)$, ζ being the constant angle between the normals to Σ and Σ' and β being termed the Bäcklund parameter. Sophus Lie subsequently observed that $\mathbb{B}_\beta$ may be decomposed according to $\mathbb{B}_\beta = \mathbb{L}_\beta^{-1} \mathbb{B}_{\beta=1} \mathbb{L}_\beta$, where $\mathbb{L}_\beta$ and $\mathbb{L}_\beta^{-1}$ are Lie invariances. Thus, Lie transformations play a

crucial role in intruding the Bäcklund parameter β into the parameter-independent “Bianchi” transformation $\mathbb{B}_{\beta=1}$ to produce $\mathbb{B}_\beta$.

It was in 1892 that Luigi Bianchi in his masterly paper *Sulla Trasformazione di Bäcklund per le Superficie Pseudosferiche* established that the BT $\mathbb{B}_\beta$ admits a commutation property $\mathbb{B}_{\beta_2} \mathbb{B}_{\beta_1} = \mathbb{B}_{\beta_1} \mathbb{B}_{\beta_2}$, a consequence of which is a nonlinear superposition principle embodied in what is termed a “permutability theorem.”

Bianchi’s Permutability Theorem

If ω is a seed solution of the sine-Gordon equation (1), let ω_1, ω_2 denote the BT of ω via $\mathbb{B}_{\beta_1}$ and $\mathbb{B}_{\beta_2}$, that is, $\omega_1 = \mathbb{B}_{\beta_1}(\omega)$ and $\omega_2 = \mathbb{B}_{\beta_2}(\omega)$. Let $\omega_{12} = \mathbb{B}_{\beta_2}(\omega_1)$ and $\omega_{21} = \mathbb{B}_{\beta_1}(\omega_2)$. Then, imposition of the commutativity requirement $\omega_{12} = \omega_{21}$ yields a new solution of (1), namely

$$\begin{aligned} \Omega &= \omega_{12} = \omega_{21} \\ &= \omega + 4 \tan^{-1} \left[\frac{\beta_2 + \beta_1}{\beta_2 - \beta_1} \tan\left(\frac{\omega_2 - \omega_1}{4}\right) \right]. \end{aligned} \quad (4)$$

This result is commonly encapsulated in what is termed a “Lamb diagram” as shown in Figure 1. This solution-generation procedure may be iterated via what is sometimes termed a Bianchi lattice. At each iteration, a new Bäcklund parameter β_i is introduced.

The discovery of the BT for the iterative construction of pseudospherical surfaces along with its concomitant permutability theorem led to an intensive search by geometers at the turn of the 20th century for other classes of privileged surfaces that possess Bäcklund-type transformations. In this connection, Luther Eisenhart, in the preface to his monograph *Transformations of Surfaces* published in 1922, asserted that: “During the past twenty-five years many of the advances in differential geometry of surfaces in Euclidean space have had to do with transformations of surfaces of a given type into surfaces of the same type.” Thus,

Figure 1. The Lamb diagram.

distinguished geometers such as Bianchi, Calapso, Darboux, Demoulin, Guichard, Jonas, Tzitzeica, and Weingarten all conducted extensive investigations into various classes of surfaces that admit BTs.

The particular Lamé system descriptive of triply orthogonal systems in the case when one of the constituent coordinate surfaces is pseudospherical was shown by Bianchi (1885) to admit an auto-BT, that is, a BT that renders the system invariant. Bianchi followed this in 1890 with the construction of a BT for the Gauss–Mainardi–Codazzi system associated with the class of hyperbolic surfaces with Gaussian curvature $\mathcal{K} = -1/\rho^2$ subject to the constraint

$$\rho_{uv} = 0, \quad (5)$$

where u, v are asymptotic coordinates. In 1899, Gaston Darboux constructed a BT for the nonlinear system

$$\begin{aligned} \theta_{xx} + \theta_{yy} + \kappa_1 \kappa_2 e^{2\theta} &= 0, \\ \kappa_{1,y} + (\kappa_1 - \kappa_2) \theta_y &= 0, \\ \kappa_{2,x} + (\kappa_2 - \kappa_1) \theta_x &= 0 \end{aligned} \quad (6)$$

descriptive of isothermic surfaces with fundamental forms

$$\text{I} = e^{2\theta} (dx^2 + dy^2), \quad \text{II} = e^{2\theta} (\kappa_1 dx^2 + \kappa_2 dy^2), \quad (7)$$

where κ_1, κ_2 are principal curvatures and x, y are conjugate coordinates. The classical BT for system (6) has been set in a modern solitonic context by Cieřliński (1997).

In the first decade of the 20th century, the Romanian geometer Gheorghe Tzitzeica embarked upon an investigation of an important class of surfaces for which, in asymptotic coordinates, the Gauss–Mainardi–Codazzi system reduces to the nonlinear hyperbolic equation

$$(\ln h)_{uv} = h - h^{-2} \quad (8)$$

to be rediscovered some 70 years later in a soliton context. Tzitzeica (1910) not only constructed a BT for (8) but also set down what, in modern terms, is a linear representation containing a spectral parameter. Tzitzeica surfaces may be subsumed in the more general

class of projective minimal surfaces for which BTs can be established (Rogers & Schief, 2002). In particular, this class contains the Demoulin system (1933)

$$(\ln h)_{uv} = h - \frac{1}{hk}, \quad (\ln k)_{uv} = k - \frac{1}{hk}. \quad (9)$$

The application of BTs in physics began with the work of Seeger et al. (1953) on crystal dislocation theory. Therein, within the context of Frenkel and Kontorova’s dislocation theory, the superposition of so-called “eigenmotions” was obtained via the permutability relation (4). The interaction of what are today called breathers with kink-type dislocations was both described analytically and displayed graphically. The typical solitonic features to be subsequently discovered for the Korteweg–de Vries (KdV) equation

$$u_t + 6uu_x + u_{xxx} = 0, \quad (10)$$

(namely, preservation of velocity and shape following interaction as well as the concomitant phase shift) were all recorded. Bianchi’s permutability theorem was subsequently employed in an investigation of the propagation of ultrashort optical pulses in a resonant medium by Lamb (1971).

A BT for the Korteweg–de Vries equation (10), namely

$$\begin{aligned} (\Lambda + \Lambda')_x &= \beta - \frac{1}{2}(\Lambda - \Lambda')^2, \\ (\Lambda' + \Lambda')_t &= (u - u')(u_{xx} - u'_{xx}) \\ &\quad - 2(u'_x + u_x u'_x + u_x'^2), \end{aligned} \quad (11)$$

where

$$\Lambda = \int_{-\infty}^x u(\sigma, t) d\sigma \quad (12)$$

was established by Wahlquist and Estabrook (1973). The spatial part of the BT was used to construct a permutability theorem, whereby multi-soliton solutions may be generated. This permutability theorem makes a remarkable appearance in numerical analysis as the so-called ε -algorithm.

A BT for the celebrated nonlinear Schrödinger (NLS) equation

$$iq_t + q_{xx} + 2|q|^2 q = 0 \quad (13)$$

was established by Lamb (1974) employing a direct method due to Clairin (1902) and by Chen (1974) via the inverse scattering transform (IST) formalism. The BT adopts the form

$$\begin{aligned} q_x + q'_x &= (q - q')(4\beta^2 - |q + q'|^2)^{1/2}, \\ q_t + q'_t &= i(q_x - q'_x)(4\beta^2 - |q + q'|^2)^{1/2} \\ &\quad + \frac{i}{2}(q + q')(|q + q'|^2 + |q - q'|^2), \end{aligned} \quad (14)$$

the spatial part of which may be used to construct a permutability theorem (Rogers & Shadwick, 1982).

Crum's theorem may be adduced to show that, at the level of the linear representation of soliton equations, the action of the BT is to add a discrete eigenvalue to the spectrum. The role of BTs in the context of the IST and their action on reflection coefficients is treated in detail by Calogero and Degasperis (1982).

That the Toda lattice equation

$$\ddot{y}_n = \exp[-(y_n - y_{n-1})] - \exp[-(y_{n+1} - y_n)] \quad (15)$$

admits a BT, namely

$$\begin{aligned} \dot{y}_n - \dot{y}'_{n-1} &= \beta [\exp\{-(y'_n - y_n)\} \\ &\quad - \exp\{(y'_{n-1} - y_{n-1})\}], \\ \dot{y}'_n - \dot{y}_n &= \beta^{-1} [\exp\{-(y_{n+1} - y'_n)\} \\ &\quad - \exp\{-(y_n - y'_{n-1})\}] \quad (16) \end{aligned}$$

was established by Wadati and Toda (1975). BTs for a range of integrable differential-difference as well as integro-differential equations may be conveniently derived via Hirota's bilinear operator approach (see Rogers & Shadwick, 1982).

BTs have by now been constructed for the gamut of known solitonic equations as well as their Painlevé reductions (Gromak, 1999). The importance of BTs in soliton theory with regard to such aspects as multi-soliton generation, geometric connections, and integrable discretization is well established. Moreover, BTs also have extensive applications in continuum mechanics (Rogers & Shadwick, 1982). Important connections between infinitesimal BTs as originally introduced in a gas dynamics context (Loewner, 1952) and the construction of 2 + 1 dimensional solitonic systems have also been uncovered.

BALL LIGHTNING Properties

Ball lightning is an impressive natural phenomenon for which there is yet no accepted scientific explanation. It consists of flaming balls or fireballs, usually bright white, red, orange, or yellow, which appear unexpectedly sometimes near the ground, following the discharge of a lightning flash, or in midair coming from a cloud.

Most observations of ball lightning are associated with thunderstorms, and they exhibit the following more detailed properties: (i) Their shape is usually spherical or spheroidal with diameters between 10 and

50 cm. (ii) They tend to move horizontally. (iii) The observed distribution of lifetimes has a most probable value between 2 and 5 s and an average value of about 10 s or higher (some cases of more than 1 min having been reported). (iv) Ball lightning is bright enough to be clearly seen in daylight, the visible output being in the range 10–150 W (similar to that of a home electric light bulb). (v) Some balls have appeared within aircraft, traveling inside the fuselage along the aisle from front to rear. (vi) There are reports of odors, similar to those of ozone, burning sulfur, or nitric oxide, and of sounds, mainly hisses, buzzes, or flutters. (vii) Most balls decay silently, but some expire with an explosion. (viii) Ball lightning has killed or injured people and animals and damaged trees, buildings, cars, and electric equipment. (ix) Fires have been started showing that there is something hot inside. In such events, the released energy has been estimated to be between 10 kJ and more than 1 MJ. (x) Ball lightning has never been produced in laboratories, in spite of many attempts and some interesting results, including anode spots and luminous objects that decay very quickly. Consequently, the properties of ball lightning are derived from reports by witnesses, who are often excited by the phenomenon and have no scientific training.

A possibly related phenomenon has been observed in submarines, after a short circuit of the batteries. Balls of plasma that float in air for several seconds have appeared at the electrodes. On these occasions, the current was about 150 kA and the energy was estimated to be between 200 and 400 kJ.

Classification of the Models

Three main characteristics must be accounted for by a successful model but seem very difficult to explain: the tendency toward horizontal motion (hot air or plasma in air tends to rise), relatively long lifetimes, and contradictions among witnesses. For example, some report that balls are cold since they did not feel any warmth when one passed nearby, while others were burned and needed medical care.

The many different models proposed to explain the phenomenon can be classified into two groups, according to whether the energy source is internal or external. In the first group, some are based on plasmoids (equilibrium configurations of plasmas), high-density plasmas with quantum mechanical properties, closed loops of currents confined by their own magnetic field (in some cases, the linking of the currents playing an important role), vortex structures as whirlwinds or rotating spheres, bubbles containing microwave radiation, chemical reactions or combustion, fractal structures, aerosols, filaments of silicon, carbon nanotubes, nuclear processes, or new physics, and even primordial mini black holes. In the second group, some assume

that the balls are powered by electrical discharges or by high-frequency microwave focused from thunderclouds. None of them is generally accepted.

Chemical and Electromagnetic Models

The association of ball lightning with electrical discharges suggests strongly that they have an electromagnetic nature. However, Michael Faraday argued that ball lightning cannot be an electric phenomenon as it would decay almost instantaneously, in contrast to its observed lifetime of at least several seconds. Finkelstein & Rubinstein (1964) used the time-independent magnetic virial theorem to place a stringent upper limit to the energy of a fireball. This limit has been viewed as a compelling argument against electromagnetic models, stimulating non-electromagnetic chemical approaches.

Recently, aerosol models have received considerable attention. In one model (Abrahamson & Dinness, 2000), a lightning discharge vaporizes silicon dioxide in the soil that—after interacting with carbon compounds—is transformed into pure silicon droplets of nanometer scale. These droplets become coated with an insulating coat of oxides and are polarized, after which they become aligned with electric fields and form networks of filaments, in loose structures called “fluff balls.” In another model (Bychkov, 2002), the discharges pick up organic material from the soil and transform it into a kind of “spongy ball” that can hold electric charges. Models of this type fail to explain that some balls appear in mid air, where there is neither silicon nor organic nor any other similar material.

Electromagnetic models that include chemical effects are promising candidates for an explanation of ball lightning. Indeed, there are now counterarguments to the three main objections that express Faraday’s argument in modern language. These are based on the radiated output, the pinch effect, and magnetic pressure.

The first objection is that the power emitted by a plasma of the size of a ball lightning is too high (one liter of air plasma at 15,000 K emits about 5 MW, several orders of magnitude too much). This may be, however, an indication that most of the ball is at ambient temperature, only a small fraction being hot, concentrated in filamentary structures (as hot current streamers). If this fraction is of the order of 1 ppm, the radiated output would be of the order of 10–100 W, in agreement with reports.

But the solution to the first problem raises another one. Any plasma current channel inside the ball would be necked and cut in a very short time by the pinch effect (the Lorentz force); thus, a ball structured by such currents could not last long enough. However, in 1958, Chandrasekhar and Woltjer showed in an astrophysical context that plasmas relax to minimum energy states, verifying the condition that the electric current and

the magnetic field are parallel so $\nabla \times \mathbf{B} = \lambda \mathbf{B}$, in which there can be no pinch effect since the Lorentz force vanishes. They concluded that such states, known as force-free fields, can confine large amounts of magnetic energy. Although the minimum energy of an unconfined plasma (as in ball lightning) is zero and corresponds to an infinitely expanded magnetic field, an almost force-free condition could be attained first in a very short time at a finite radius, a slow expansion continuing afterward with negligible pinch effect. This could take several seconds.

The third objection is based on the magnetic virial theorem, which states that a system of charges in electromagnetic interactions has no equilibrium state in the absence of external forces, because the large magnetic pressure must produce an explosion with no other force to compensate it. But it is not certain that the fireballs are in equilibrium; they could be just in metastable states with slow evolution, the streamers, moreover, clearly not being in equilibrium themselves. Still more important, the force-free condition annihilates the magnetic pressure or at least reduces it to a much smaller value if the field is almost force-free. Furthermore, the problem needs a much more complex analysis than has been offered up to now. For instance, one must include the thermochemical and quantum effects on the transport processes in the plasma as well as other nonlinear effects.

Faddeev and Niemi (2000) have proposed compelling arguments that challenge certain widely held views on plasmas, showing that the virial theorem does allow nontrivial equilibrium states of streamers and electromagnetic fields inside a background of plasma, which are "topologically stable solitons that describe knotted and linked flux tubes of helical magnetic fields." This kind of configuration was proposed in 1998 by Rañada et al. (2000) in the context of ball lightning. Therefore, it seems that the virial theorem does not necessarily support Faraday's view.

That ball lightning may contain force-free magnetic configurations of plasmas seems plausible. Because electric conduction in air proceeds through thin channels called streamers—as happens in ordinary lightning—it can be imagined that plasma inside the fireball consists of a self-organized set of metastable, highly conductive, wire-like or filamentary currents. Furthermore, unusually long-lived filaments (even closed loops) in high-density structures have been theoretically predicted and experimentally observed in many plasma systems within a great range of length scales, for instance, in astrophysics, tokamaks, and ordinary discharges in air. Thus, filamentary structures are currently receiving considerable attention.

The strongly nonlinear behavior of a plasma is enhanced when filamentary structures appear, leading to a complex non-isotropic system, which should be studied within a more general theory than

ideal magnetohydrodynamics (MHD). Still, the main features of such systems can be described in the framework of resistive MHD. The important dissipative effects depend on the transport coefficients, such as thermal and electrical conductivities, which are highly nonlinear functions of the electromagnetic fields and the temperature, as well as of the chemical and quantum properties.

From the point of view of the MHD approximation, the dimensionless parameters of the plasma inside ball lightning may be quite similar to those found in other plasma scenarios, implying stable or metastable currents along a set of closed loops in filamentary structures. An interesting and unexplored possibility is the establishment, inside the streamers, of a quasicollision-free highly conductive regime in the direction of the magnetic field, which is strong and parallel to the streamers axis. In such a regime, both the electric and the thermal conductivities would become highly anisotropic. The first would be considerably enhanced along the axis of the streamer. On the other hand, both conductivities would be greatly reduced in the transverse directions, behaving as $1/B^2$ according to classical predictions. In this way, the dissipation and the spreading in the streamers would be much smaller than in ordinary regimes and should produce a long-lived strongly magnetized global plasma structure within an intricate stabilizing topology of filamentary currents.

In summary, even though the phenomenon of ball lightning has been known for many years, there is still no accepted theory to explain it—the alternatives currently most favored being the chemical and the electromagnetic models. The latter seem promising now, after recent results showed that some classical objections are not always applicable. As an example, a number of filamentary plasma structures have generated considerable interest, which are similar to stable plasma scenarios observed in nature, for instance, in astrophysics. These kinds of models could possibly embody chemical and electromagnetic elements.

BELOUSOV–ZHABOTINSKY REACTION

In 1950, Boris Pavlovich Belousov worked at the Institute of Biophysics of the Ministry of Public Health of the USSR when he observed that the reaction between citric acid, bromate ions, and ceric ions (as catalyst) produced a regular periodic and reproducible change of color between an oxidized state and a reduced state. A temporal oscillating reaction appeared like a chemical clock. His 1951 paper on this study was largely rejected by the science community because it seemed to violate the Second Law of thermodynamics.

In 1961, Anatol Zhabotinsky, a Russian postgraduate student guided by his professor, Simon Shnoll, modified the previous reaction by replacing citric acid with malonic acid and adding ferroin sulfate as an indicator. As the oxidized state of ferroin is blue and the reduced one is red, he was able to observe an oscillating temporal reaction with larger oscillating amplitudes. This reaction

was named the Belousov–Zhabotinsky (BZ) reaction. The first publications in English, recognizing the works of Belousov and Zhabotinsky, were done in 1967 by the Danish scientist Hans Degn. However, Zhabotinsky was unable to propose a complete mechanism for the system. Experimentally, the periodic evolution of the potential of the reacting solution can be followed by a potentiometric method, as shown in Figure 1.

Figure 1. A photograph showing the periodic potential obtained between a platinum electrode and a reference electrode immersed in a BZ solution.

In 1972, Richard Field, Endre Körös, and Richard Noyes, at the University of Oregon, studied this mechanism using a bromide-selective electrode to follow the reaction. They proposed 18 steps involving 21 chemical species, using the same principles of chemical kinetics and thermodynamics that govern ordinary chemical reactions—this was the FKN mechanism. In 1974, the same scientists proposed a simplified mechanism with penetrating chemical insight: the “Oregonator” (in honor of the University of Oregon).

Compound:	BrO_3^-	Organic species	HBrO
Notation:	A	B	P

Compound:	HBrO_2	Br^-	Ce^{4+}
Notation:	X	Y	Z

With these notations, the FKN mechanism is

- $A + Y \rightarrow X + P$,
- $A + X \rightarrow 2X + 2Z$,
- $X + Y \rightarrow 2P$,
- $2X \rightarrow A + P$,
- $B + Z \rightarrow (f/2)Y + \text{other products}$.

The second step is fundamental for the observation of oscillations; it is an autocatalytic reaction or retroaction loop. In the fifth step, B represents all oxidizable organic species present, and f is a stoichiometric factor. The kinetic differential equations are:

$$\frac{d[X]}{dt} = k_1[A] \cdot [Y] + k_2[A] \cdot [X] - k_3[X] \cdot [Y] - 2k_4[X]^2, \quad (2)$$

$$\frac{d[Y]}{dt} = -k_1[A] \cdot [Y] - k_3[X] \cdot [Y] + 2k_5 \frac{f}{2} [B] \cdot [X], \quad (3)$$

$$\frac{d[Z]}{dt} = 2k_2[A] \cdot [X] - k_5[B][Z]. \quad (4)$$

The rate constants are:

Rate constants: Value (l/mol s):	k_1	k_2	k_3	k_4	k_5
	1.28	2.4×10^6	33.6	3×10^3	1

This system is clearly nonlinear. Solutions can be obtained by numerical methods, and for $0.5 \leq f \leq 2.4$, some oscillating temporal solutions are observed, whose solutions depend on the initial conditions. According to the Second Law of thermodynamics, all spontaneous chemical changes in a homogeneous and closed system involve a decrease in free enthalpy of this system. If a fluctuation disrupts the system close to equilibrium, the system will return irrevocably to this stable state, making oscillations impossible. Nonetheless, it is possible to observe oscillations when the system is far from equilibrium. One of the striking properties of nonlinear systems is the effect of fluctuations (of the concentrations of intermediates), which can transform an unstable system into new states that are more organized than the initial state. Ilya Prigogine (who was awarded the 1977 Nobel Prize in chemistry for his work on thermodynamics) gave the name “dissipative structures” to such systems to emphasize the importance of irreversible phenomena far from equilibrium.

Continuing to work on oscillating reactions, in 1970, Zhabotinsky published, with Zaikin, a paper that announced the existence of two-dimensional waves in the BZ reaction; also in 1972, Arthur Winfree observed spiral wave patterns in a BZ reaction (see Figure 2). This reaction took place without stirring in a thin (approximately 2 mm thick) layer of reactants poured into a Petri dish. Blue concentric circles (called targets) radiated across the dish on a red background and self-generating spirals appeared. Soon afterward, scientists reported that a blue target center can produce waves of oxidation propagating through the reduced medium, and as the waves advance toward the interior of the center, they transform from red to blue. The period of oscillation is variable, but the speed of propagation is roughly constant. Thus, the BZ reaction proves to be a stationary spatiotemporal oscillating reaction.

With the aid of the FKN mechanism, Field and Noyes showed how to understand the development of such target waves. The diffusion is the transport of species from the areas of high concentrations to those of low concentrations. When there is a coupling between a chemical reaction with an autocatalytic step (or feedback-retroaction loop) as in the BZ reaction with the diffusion of species, spatial organization phenomena can occur; thus these are called “reaction-diffusion systems.” In such systems, molecules react chemically with each other when they collide, and as

Figure 2. Spiral waves in a BZ reaction (Courtesy of A.T. Winfree). See text for details.

the concentrations of components change, a chemical wave propagates.

In 1984, Oleg Mornev (at the Institute of Theoretical and Experimental Biophysics of the Russian Academy of Sciences) showed that in an infinite plane stationary system of reaction-diffusion oscillations, Snell’s sine law of refraction was verified. Thus the simple rule

$$\frac{\sin \psi_1}{\sin \psi_2} = \frac{v_1}{v_2} \quad (5)$$

dictates the angles ψ_1 and ψ_2 when waves hit an interface separating two regions with different speeds (v_1 and v_2) of wave propagation. This result was surprising because reaction-diffusion systems are nonlinear; thus, the medium is an active and an integral part of the wave. In fact, ψ_1 cannot be set arbitrarily but is slaved with ψ_2 due to the nature of the two regions.

In 1993, Zhabotinsky (at the Department of Chemistry, Brandeis University) demonstrated Snell’s law experimentally. In 1998, Rui Dilaô and Joaquim Sainhas (at the Instituto Superior Tecnico, Lisbon Portugal) showed the following constraint in a reaction-diffusion system: after the reaction, the medium must be chemically identical to its initial form. In other words, while the waves are propagating and reactions are taking place, the medium has different properties, but these waves transform the medium back to the original species. By solving reaction-diffusion equations under this constraint, Dilaô and Sainhas showed (using computer simulations) that their formulation agrees with experiments, and mathematically chemical waves obey Snell’s sine law. Continuing to work on the phenomenon of refraction, Mornev is developing formulations that hold both in infinite and finite media.

There are other examples of reaction-diffusion systems. In 1983, Patrick de Kepper (a French chemist in Toulouse) highlighted Turing structures

in a ClO_2^- , I^- , malonic acid reaction (CIMA reaction). In Turing structures, stationary zones of varying concentrations appear in space. For these observations, the reaction must have steps with retroaction loops containing activators and other steps with inhibitors, and the activators must diffuse more slowly than the inhibitors.

Although the intense study of oscillating chemical reactions and nonlinear dynamics in chemistry is only about 30 years old, its progress has been impressive. Depending on the initial conditions, the BZ reactions can have unpredictable behaviors, even though they are described by deterministic laws. Thus, the BZ reaction belongs to the group of physical or chemical systems that exhibits deterministic chaos.

BERNOULLI'S EQUATION

Bernoulli's equation is possibly the best-known result in fluid mechanics—and the most frequently abused. Bernoulli's equation may be viewed as an energy-conservation budget for a fluid particle as it travels up and down the "hills" of potential energy, due to the fields of gravity and the pressure within the fluid, acquiring and relinquishing kinetic energy. In its simplest form, it states that

$$V^2/2 + p/\rho + gz = C, \quad (1)$$

where p is the pressure in the fluid of density ρ , V is the flow speed, and z is the vertical coordinate. (The flow takes place in a uniform gravitational field of acceleration g .) The sum on the left-hand side of Equation (1) is a constant, C . The first term is the kinetic energy of the fluid per unit mass, the second and third terms are the potential energy (again per unit mass) in the combined energy "landscape" of pressure and gravity.

The result is credited to Daniel Bernoulli (1700–1782), son of Johann Bernoulli (1667–1748), and to his monograph *Hydrodynamica*, initiated in 1729 and ultimately published in 1738. The history of the equation is, however, much richer than this simple sequence of events would suggest. Hunter Rouse puts the issues this way in a book containing English translations of the writings of both the son and the father:

Why [these] works should have been singled out for translation seems at first sight rather obvious, if only because of the frequency with which the name Bernoulli is on the hydraulician's lips. But it is only Daniel to whom one is making reference, and the word is gradually spreading that the theorem bearing his name is nowhere to be found in his habitually cited *Hydrodynamica*. Not until the last few years has mention of either the work *Hydraulica* or its author Johann Bernoulli appeared in the fluids literature with any frequency, and this almost exclusively in the writings of C. Truesdell. It is Truesdell's thesis that, whereas Daniel has received too much credit for the formulation of the Bernoulli theorem, Johann has received too little. (Carmody et al., 1968).

A complicated set of circumstances ensued in which both father (Johann) and son (Daniel) sent their manuscripts to Leonhard Euler for comment and this led to Johann's manuscript, which appears to have been composed later than Daniel's, being published in the *Memoirs of the Imperial Academy of Science in St. Petersburg* in 1737 and 1738 (although these were not printed until a decade later). Indeed, Johann's treatise first appeared in his collected works published in Switzerland in 1743. While Daniel's treatise has the gist of what we today call Bernoulli's equation, Johann's treatment is more mature and complete.

In the form stated in Equation (1), Bernoulli's equation applies only to steady, constant-density, irrotational flow, that is, to a flow pattern that is unchanging in time and that has no vorticity.

More refined versions may be derived. Thus, in a steady, constant-density flow with vorticity, Equation (1) still holds along each streamline, but the "constant" on the right-hand side may vary from streamline to streamline. Indeed, the gradient of this changing "Bernoulli constant," ∇C , equals the Lamb vector, the vector product of flow velocity and vorticity,

$$\mathbf{V} \times \boldsymbol{\omega} = \nabla C.$$

If the flow is irrotational but unsteady, a version of Bernoulli's equation again holds, but the constant on the right-hand side of (1) is replaced by (minus) the time derivative of the velocity potential. (In an irrotational flow, the velocity field is the gradient of a scalar known as the velocity potential.) With $V = -\nabla\phi$, where ϕ is the velocity potential, we obtain Bernoulli's equation in the form

$$(\nabla\phi)^2/2 + p/\rho + gz = -\frac{\partial\phi}{\partial t}, \quad (2)$$

which, coupled with the condition of irrotational flow,

$$\Delta\phi = 0, \quad (3)$$

gives a system of two partial differential equations for the fields p and ϕ .

Bernoulli's equation in the simplistic form "high flow speed implies low pressure and vice versa" is often applied as a first, crude explanation of many flow phenomena from the ability to balance a ball atop a plume of air to the lift on an airfoil in flight. Some of these explanations are too simplistic, not to say incorrect. Nevertheless, Bernoulli's equation, when properly applied under the assumptions that ensure its validity, can be an extremely useful and powerful tool of fluid flow analysis.

It is remarkable—and important to note—that Bernoulli's equation (1) is not invariant to a Galilean transformation, ordinarily a prerequisite for a physical law to be useful. Thus, if one wants to use Bernoulli's equation (1) to calculate the pressure distribution for flow around an object, assuming the velocity field is known, it is essential to do so in a frame of reference in which the flow satisfies the necessary assumptions, in particular, that the flow is steady. The correct result is obtained by carrying out such a calculation in a frame of reference moving with the body. If the calculation is attempted in the "laboratory frame" through which the object is moving, one has to tackle the much more complex version of Bernoulli's equation given in (2). If the version in Equation (1) is applied, one obtains an incorrect result.

BERRY'S PHASE

Consider the parallel transport of an orthonormal frame along a line of constant latitude on the surface of a sphere. In going once around the sphere, the frame undergoes a rotation through an angle $\Delta\theta = 2\pi \cos\alpha$, where α is the colatitude. This may be shown using the geometry of Figure 1. As is also evident from the figure, this phase shift is purely geometric in character—it is independent of the time it takes to traverse the closed loop.

This construction underlies the well-known phase shift exhibited by the Foucault pendulum as the Earth rotates through one full period. Although arising through a dynamical process involving two widely separated time scales (the period of the Earth's rotation and the oscillation period of the pendulum), the phase shift in this and other examples is now understood in a more unified way. *Holonomic* effects such as these arise in a host of applications ranging from problems in superconductivity theory, fiber optic design, magnetic resonance imaging (MRI), amoeba propulsion and robotic locomotion and control, micromotor design, molecular dynamics, rigid-body motion, vortex dynamics in incompressible fluid flows (Newton, 2001), and satellite orientation control. For a survey and further references on the use of phases in locomotion problems, see Marsden & Ostrowski (1998).

That the falling cat learns quickly to re-orient itself optimally in mid-flight while maintaining zero angular momentum is a manifestation of the fact that controlling and manipulating a system's internal or shape variables can lead to phase changes in the external, or group variables, a process that can be exploited and has deeper connections to problems related to the dynamics of Yang–Mills particles moving in their associated gauge field, a link that is the *falling cat theorem* of Montgomery (1991a) (see further discussion and references in Marsden (1992) and Marsden & Ratiu (1999)). One can read many of the original articles leading to our current understanding of the geometric phase in the collection edited by Shapere & Wilczek (1989).

Problems of this type have a long and complex history dating back to work on the circular polarization of light in an inhomogeneous medium by Vladimirkii and Rytov in the 1930s and by Pancharatnam in the 1950s, who studied interference patterns produced by plates of

Figure 1. Parallel transport of a frame around a line of latitude.

an anisotropic crystal. Much of this early history is described in the articles by Michael Berry (Berry, 1988, 1990). The more recent literature was initiated by his earlier articles (Berry, 1984, 1985), which investigated the evolution of quantum systems whose Hamiltonian depends on external parameters that are slowly varied around a closed loop. The adiabatic theorem of quantum mechanics states that for infinitely slow changes of the parameters, the evolution of the complex wave function, governed by the time-dependent Schrödinger equation, is instantaneously in an eigenstate of the *frozen* Hamiltonian. At the end of one cycle, when the parameters recur, the wave function returns to its original eigenstate, but with a phase change that is related to the geometric properties of the closed loop. This phase change now goes by the name *Berry's phase*. Geometric developments started with the work of Simon (1983), and Marsden et al. (1989). One can introduce a bundle of eigenstates of the slowly varying Hamiltonian, as well as a natural *connection* on it; the Berry phase is then the bundle holonomy associated with this connection, while the curvature of the connection, when integrated over a closed two-dimensional (2-d) surface in parameter space gives rise to the first Chern class characterizing the topological twisting of this bundle.

The classical counterpart to Berry's phase was originally developed by Hannay (1985) (hence the terminology *Hannay's angle*) and is most naturally described by considering slowly varying integrable Hamiltonian systems in action-angle form. If we let $(I_1, \dots, I_n; \theta_1, \dots, \theta_n)$ represent the action-angle variables of a given integrable system, then the governing Hamiltonian can be expressed as $\mathcal{H}(I_1, \dots, I_n; R(t))$, where $R(t)$ is a slowly varying parameter that cycles through a closed loop in time period T , that is, $R(t + T) = R(t)$, $\dot{R}(t) \sim \varepsilon R$, $\varepsilon \ll 1$. The configuration space for the system is an n -dimensional torus $\mathbb{T}^n$ and we seek a formula for the angle variables as the parameter or parameters slowly evolve around the closed loop $\mathcal{C}$ in parameter space. The time-dependent system is governed by

$$\dot{\mathbf{I}} = \dot{R}(t) \cdot \frac{\partial \mathbf{I}}{\partial R}, \quad (1)$$

$$\dot{\boldsymbol{\theta}} = \boldsymbol{\omega}(\mathbf{I}) + \dot{R}(t) \cdot \frac{\partial \boldsymbol{\theta}}{\partial R}, \quad (2)$$

where

$$\boldsymbol{\omega}(\mathbf{I}) \equiv \frac{\partial \mathcal{H}}{\partial \mathbf{I}}.$$

Since R is slowly varying, we can average the system around level curves of the frozen (i.e., $\varepsilon = 0$) Hamiltonian. If we let $\langle \cdot \rangle$ denote this phase-space average, then the averaged canonical system becomes

$$\dot{\mathbf{I}} = \dot{R}(t) \cdot \left\langle \frac{\partial \mathbf{I}}{\partial R} \right\rangle \quad (3)$$

$$\dot{\boldsymbol{\theta}} = \boldsymbol{\omega}(\mathbf{I}) + \dot{R}(t) \cdot \left\langle \frac{\partial \boldsymbol{\theta}}{\partial R} \right\rangle. \quad (4)$$

The well-known adiabatic theorem of quantum mechanics guarantees that the action variable is nearly constant due to its adiabatic invariance, whereas the angle variables can be integrated over period T

$$\theta_T^i = \int_0^T \omega^i(\mathbf{I}) dt + \int_0^T \dot{R}(t) \cdot \left\langle \frac{\partial \theta^i}{\partial R} \right\rangle dt \quad (5)$$

$$= \theta_d + \theta_g. \quad (6)$$

The first term, θ_d , called the dynamic phase is due to the frozen system, while the second term, θ_g , arises from the time variation. This geometric phase can be rewritten in a revealing manner as

$$\theta_g = \int_0^T \dot{R}(t) \cdot \left\langle \frac{\partial \theta^i}{\partial R} \right\rangle dt \quad (7)$$

$$= \oint \left\langle \frac{\partial \theta^i}{\partial R} \right\rangle dR. \quad (8)$$

The contour integral is taken over the closed loop $\mathcal{C}$ in parameter space. Although arising through a dynamical process, it is ultimately a purely geometric quantity that results from a delicate balance of two compensating effects in the limit $\varepsilon \rightarrow 0$. On the one hand, $T \rightarrow \infty$ in (7), while on the other, $\dot{R}(t) \rightarrow 0$. Their rates exactly balance so that the integral leaves a residual term in the limit $\varepsilon = 0$, as given in (8).

A nice example developed in Hannay (1985) is the *bead-on-hoop* problem in which a frictionless bead is constrained to slide along a closed planar wire hoop that encloses area $\mathcal{A}$ and has perimeter length $\mathcal{L}$. As the bead slides around the hoop, the hoop is slowly rotated about its vertical axis (which is aligned with the gravitational vector) through one full revolution. We are interested in the angular position of the bead with respect to a fixed point on the hoop after one full revolution of the hoop. When compared with its angular position had the hoop been held fixed (the frozen problem), this angle difference would represent the geometric phase and is given by

$$\Delta\theta = -8\pi^2 \mathcal{A} / \mathcal{L}^2. \quad (9)$$

Montgomery (1991b) shows that modulo 2π , we have the following *rigid-body phase formula*:

$$\Delta\theta = -\Lambda + 2ET/R. \quad (10)$$

Figure 2. The geometry of the rigid-body phase formula.

Let us explain the notation in this remarkable formula. When a rigid body is freely spinning about its center of mass, one learns in mechanics that this dynamics can be described by the Euler equations, which are equations for the body angular momentum Π . This vector in $\mathbb{R}^3$ moves on a sphere (of radius $R = \|\Pi\|$) and describes periodic orbits (or exceptionally, heteroclinic orbits). This orbit is schematically depicted by the closed curve on the sphere shown in Figure 2. However, the full dynamics includes the dynamics of the rotation matrix for describing the attitude of the rigid body as well as its conjugate momentum. There is a projection from the full dynamic phase space (which is 6-d) to the body angular momentum space (which is 3-d). After one period of the motion on the sphere, the actual rigid-body motion was not periodic, but it had rotated about the spatial angular momentum vector by an angle $\Delta\theta$, the left-hand side of the above formula. The quantity Λ is the spherical angle subtended by the cap shown in the figure, E is the energy of the trajectory, and T is the period of the closed orbit on the sphere. A detailed history of this formula is given in Marsden & Ratiu (1999).

BETHE ANSATZ

The Bethe ansatz is the name given to a method for exactly solving quantum many-body systems in one spatial dimension (1-d) or classical statistical lattice models (vertex models) in two spatial dimensions (Baxter, 1982; Korepin et al., 1993). The method was developed by Hans Bethe in 1931 (Bethe, 1931) in order to diagonalize the Hamiltonian of a chain of N spins with isotropic exchange interactions, introduced by Werner Heisenberg some years before as the simplest model for a 1-d magnet. This result was achieved by assuming the wave function to be of the form

$$f(x_1, x_2, \dots, x_M) = \sum_P A_P e^{i \sum_{j=1}^M k_{P_j} x_j} \quad (1)$$

with the sum performed on all possible permutations P of M distinct wave numbers $\{k_1, \dots, k_M\}$, corresponding to down spins in the system (Bethe ansatz). By imposing invariance under the physical symmetries of the system (discrete translations and total spin rotations), Bethe obtained conditions on the coefficients A_P , which were satisfied if a set of M nonlinear equations (Bethe equations) in N complex parameters (Bethe numbers) were fulfilled. Surprisingly, the wave functions thus constructed were simultaneous eigenfunctions not only of the translation operator, the total spin S_z , and its projection S_z along the z -direction but also of the isotropic Heisenberg Hamiltonian

$$H = \sum_{i=1}^N \left(S_i \cdot S_{i+1} - \frac{1}{4} \right). \quad (2)$$

The energy and the crystal momentum were expressed as symmetric functions of the Bethe numbers; thus, the eigenvalue problem for H was reduced to the solution of an algebraic problem—solution of the Bethe equations.

This remarkable result was possible because of the existence of additional symmetries of the Heisenberg Hamiltonian, which emerged thanks to the ansatz made by Bethe on the wave function. In this original formulation, the method is known as the coordinate Bethe ansatz.

Progress in clarifying the role of symmetries in the Bethe ansatz, the link with integrable systems, and the algebraic aspect of the method was achieved by the Saint Petersburg (formerly Leningrad) School in the course of developing the quantum inverse scattering method (QISM) (Faddeev, 1984; Sklyanin & Faddeev, 1978; Korepin et al., 1993), after the work of Baxter on the integrability of vertex models (Baxter, 1982). In this approach, a key role is played by the monodromy operator defined as $\tau(\lambda) = L_N(\lambda)L_{N-1}, \dots, L_1(\lambda)$, with λ being a complex number (spectral parameter) and $L_n(\lambda)$ being the quantum local Lax operator defined for the isotropic Heisenberg model as

$$L_n(\lambda) = \begin{pmatrix} \lambda + iS_n^z & iS_n^- \\ iS_n^+ & \lambda - iS_n^z \end{pmatrix} \quad (3)$$

with S^+ , S^- raising and lowering spin- $\frac{1}{2}$ operators. Note that L_n can be viewed as an operator acting on the space $h_n \otimes V$, where $h_n (\equiv C^2)$ is the physical Hilbert at site n (the space of couples of complex numbers), and V is an auxiliary space related to the matrix representation of L_n (for the present case, V is also identified with C^2). The product of Lax operators, taken in the auxiliary space, coincides with the usual matrix multiplication, so that the monodromy matrix can be rewritten as

$$\tau(\lambda) = \begin{pmatrix} A(\lambda) & B(\lambda) \\ C(\lambda) & D(\lambda) \end{pmatrix}, \quad (4)$$

with A, B, C, D operators acting on the full physical Hilbert space: $H = \prod \otimes h_i$. As is known from QISM (Korepin et al., 1993; Sklyanin & Faddeev, 1978; Faddeev, 1984), the commutation relations between elements of the monodromy matrix can be written in a compact form as

$$R(\lambda - \mu) (\tau(\lambda) \otimes \tau(\mu)) = (\tau(\mu) \otimes \tau(\lambda)) R(\lambda - \mu), \quad (5)$$

where R is a 4×4 matrix (quantum R-matrix) satisfying the Yang-Baxter equation. From Equation (5), it follows that the trace of the monodromy operator (also known as the transfer matrix) $T(\lambda) \equiv \text{tr}(\tau(\lambda)) = A(\lambda) + D(\lambda)$ gives rise, for different values of the spectral parameter, to an abelian algebra of operators

$$[T(\lambda), T(\mu)] = 0. \quad (6)$$

One can prove that the Hamiltonian is also an element of this algebra so that, for a system of N sites, there are N quantum integrals of motion in involution,

corresponding to Liouville integrability in the classical limit. The diagonalization of the Hamiltonian and the other integrals of motion is thus reduced to the solution of the eigenvalue problem for the transfer matrix T . This problem can be solved by the so-called algebraic Bethe ansatz, a procedure that resembles the algebraic diagonalization of the harmonic oscillator by means of creation and annihilation operators. It relies on the existence of a vector $|\Omega\rangle$ (pseudovacuum) in the Hilbert space, which is annihilated by the operator C of the monodromy matrix

$$C(\lambda)|\Omega\rangle = 0. \quad (7)$$

For the Heisenberg chain, $|\Omega\rangle$ can be chosen as $|\Omega\rangle = \prod_{i=1}^N |\uparrow\rangle_i$ with $|\uparrow\rangle_i$ denoting the spin up state at site i . From Equation (3) it is clear that L_n acts on the state $|\uparrow\rangle_n$ as a triangular matrix, and the same is true for $\tau(\lambda)$ acting on $|\Omega\rangle$; thus, Equation (7) is automatically satisfied (C plays the role of an annihilation operator). From Equations (3) and (4), it is also evident that $A(\lambda)|\Omega\rangle = (\lambda + i/2)^N |\Omega\rangle$, $D(\lambda)|\Omega\rangle = (\lambda - i/2)^N |\Omega\rangle$. Moreover, one can show that the operator B in Equation (4) can be used as a creation operator.

By taking N different values of the spectral parameter $\lambda_1, \lambda_2, \dots, \lambda_N$, one constructs a trial wave function as

$$|\Psi(\lambda_1, \dots, \lambda_N)\rangle = \prod_{i=1}^N B(\lambda_i)|\Omega\rangle. \quad (8)$$

A direct calculation shows that

$$T(\lambda)|\Psi(\lambda_1, \dots, \lambda_N)\rangle = \Lambda(\lambda)|\Psi(\lambda_1, \dots, \lambda_N)\rangle + \text{unwanted terms}, \quad (9)$$

where the unwanted terms can be calculated using the commutation relations of A and D with B , obtained from Equation (5). The unwanted terms, however, are eliminated if the λ_i are taken as solutions of the Bethe equations that, for the isotropic Heisenberg chain, are of the form

$$\begin{pmatrix} \lambda_\alpha - i/2 \\ \lambda_\alpha + i/2 \end{pmatrix}^N = - \prod_{\beta=1}^M \frac{\lambda_\alpha - \lambda_\beta - i}{\lambda_\alpha - \lambda_\beta + i}, \quad (10)$$

$$\alpha = 1, 2, \dots, M.$$

The set of states obtained from Equation (8) in correspondence of the solutions of this system of nonlinear equations can be shown to be complete. The diagonalization of $T(\lambda)$, and hence of the Hamiltonian and all the quantum integrals of motion, is thus reduced to the problem of solving the Bethe equations. For finite size systems, this is a difficult problem to solve due to the nonlinearity of the equations, and one usually resorts to numerical tools. In the thermodynamical

limit, however, it is possible to obtain exact solutions of the energy spectrum by deriving linear integral equation for the density distribution of the Bethe solutions in a complex plane (however, this requires an assumption on the nature of the solution known as the string hypothesis).

The algebraic Bethe ansatz has been successfully applied to a large class of many-body problems, including anisotropic generalizations of the Heisenberg chain, the Hubbard model, and the Kondo model, and has stimulated a variety of related approaches including Baxter's q -operator method (Baxter, 1982) and the notion of quantum groups. Recent progress in the computation of correlation functions of quantum-integrable many-body problems have also been made using the Bethe ansatz (Korepin et al., 1993).

BIFURCATIONS

Bifurcations are critical events that arise in systems when an external control parameter is varied (Arnol'd et al., 1994). For small values of the parameter the system will be linear and a unique fixed point will exist. As the parameter is changed to ranges, where nonlinearity becomes important, instabilities in the form of new fixed points or solutions with qualitatively different dynamical behavior may arise at bifurcations. These critical events are of mathematical and practical interest since their analysis can be performed, and they form organizing centers for observed dynamics (Guckenheimer & Holmes, 1986).

As an example, consider the simple physical system of a plastic ruler that is compressed lengthwise between your hands. This was first considered by Leonhard Euler in 1744 and is often referred to as the Euler strut problem (Acheson, 1997). At small forces, the ruler is approximately straight and supports the applied load.

This is called the trivial state of the system. However, as the load increases, buckling takes place so that the ruler is deflected up or down. The straight trivial state becomes unstable and is replaced by a pair of solutions where each corresponds to one of the buckled states. If the ruler and the application of the load were both perfect, this would provide a physical example of a symmetry-breaking supercritical pitchfork bifurcation of the type shown in the bifurcation diagram of Figure 1(a).

The symbol X represents the deflection of the center of the ruler, which is used as the measure of the state of the system shown plotted as a function of the applied load λ . The symmetry that is broken is the mirror-plane symmetry of the straight ruler. The bifurcation is called supercritical because the nontrivial branches have the same stability as the trivial state, and it is termed pitchfork due to its shape.

When the bifurcating solutions have a stability opposite to the trivial, the bifurcation is called subcritical. A sketch of such a bifurcation is given in Figure 1(b) where an increase in the parameter λ would involve a jump to a large X state when λ is increased beyond the critical value λ_c . In order to regain the trivial state, λ would then have to be reduced to reach the folded part of the solution branches, and a sudden change back to the trivial state would occur. Hence, hysteresis takes place between the two transitions, and such a path is labeled C in Figure 1(b). The pair of folds in Figure 1(b) are called saddle-node bifurcations (Iooss & Joseph, 1990). A physical example of this is provided by the buckling of an elastic wire such as the outer portion of a bicycle brake cable. When a short length is held vertically, it will stand upright. If you push the remaining length upward through your hand, it will eventually become long enough so that gravity will cause it to fall over through a large angle of deflection. Now pull it back downward through your hand and you will find that the deflected state remains over a range of lengths before flipping back to the vertical. This is an example of a hysteresis loop.

The two models in Figures 1(a) and (b) contain a reflection symmetry. If this is not present, the bifurcation is transcritical and an example of such a bifurcation is given in Figure 1(c). In the physical example of the buckling of the ruler, this type of bifurcation would be observed if a constant side load

Figure 1. Sketches of (a) supercritical pitchfork, (b) subcritical pitchfork and (c) transcritical bifurcations. Solid lines indicate stable solutions and dashed lines indicate unstable.

Figure 2. Imperfect pitchfork bifurcation.

Figure 3. Schematic of a gluing bifurcation sequence.

was applied in addition to the end load in the example of the ruler. In this case, the mid-plane symmetry is automatically broken.

Of course, in any real system, physical imperfections will be present. These can be taken into account using the imperfect bifurcation theory (Golubitsky & Schaeffer, 1985). The effect of an imperfection is to disconnect the supercritical pitchfork bifurcation as shown in Figure 2. It can be seen that there is one state that evolves smoothly with an increase in parameter λ and another disconnected branch. In the example of the ruler, imperfections could arise from irregularities in the shape of the ruler or a slight imbalance in the applied load. The lower limit of the disconnected branch is defined by another type of bifurcation, a saddle node. The disconnected state can be attained, either by variation of two parameters (e.g., variation of side load for the Euler strut), or by a discontinuous or sudden jump in the parameter λ . In the latter case, there is a finite chance that the system will land on the disconnected solution. Examples of observations of such behavior in fluid flows are provided by Taylor–Couette flow (Pfister et al., 1988), a flow through a sudden expansion (Fearn et al., 1990), and convection (Arroya & Saviron, 1992).

Another very important bifurcation is a Hopf where a simply periodic cycle arises from a fixed point as

a parameter is changed. As in the case of pitchforks, Hopf bifurcations may also be super- or subcritical, with hysteresis present in the latter case. An interesting feature of supercritical Hopf bifurcations is that the system takes more and more time to reach the equilibrium state as the bifurcation point nears. The observed long-term dynamics are analogous to critical slowing down (Landau & Lifshitz, 1980) in phase transitions and have been found in a fluid flow (Pfister & Gerdtz, 1981), for example.

Further interesting global bifurcations (Glendinning, 1994) may occur when pitchfork and Hopf bifurcations occur sequentially. An example of this is shown schematically in Figure 3, where the pair of asymmetric states that arise at the pitchfork P then undergo a pair of Hopf bifurcations at the points labeled H . The cycles that arise at H then join together at a gluing bifurcation (Coullet et al., 1984) when λ is increased. This point is marked G in Figure 3, and it is an example of a homoclinic bifurcation. In this case, a single large orbit is formed beyond G with the period going to infinity exactly at G . Interesting dynamical behavior including chaos can be observed near such points in experiments when physical imperfections are taken into account (Glendinning et al., 2001).

BI-HAMILTONIAN STRUCTURE

See **Integrable lattices**

BILAYER LIPID MEMBRANES

When a group of unknown researchers reported the artificial assembly of a bimolecular lipid membrane in vitro (at a 1961 symposium on the plasma membrane sponsored by the American and New York Heart Association), it was initially met with skepticism. The research group led by Donald O. Rudin began their report with a description of mundane soap bubbles, followed by “black holes” in soap films, ending with an invisible “black” lipid membrane made from extracts of cows’ brains. The reconstituted structure (7.5 nm thick) was created just like a cell membrane separating two aqueous solutions. The speaker then said:

upon adding one, as yet unidentified, heat-stable compound... from fermented egg white... to one side of the bathing solutions... lowers the resistance... by 5 orders of magnitude to a new steady state... which changes with applied potential... Recovery is prompt... the phenomenon is indistinguishable... from the excitable alga *Valonia*... and similar to the frog nerve action potential (Ottova & Tien, 2002).

The first report was published a year later (Mueller et al., 1962). In reaction to that report, the subsequent inventor of liposomes (artificial spherical bilayer lipid membranes) wrote recently in an article entitled “Surrogate cells or Trojan horses” (Bangham, 1995):

...a preprint of a paper was lent to me by Richard Keynes, then Head of the Department of Physiology [Cambridge University], and my boss. This paper was a bombshell... They [Mueller, Rudin, Tien, and Wescott] described methods for preparing a membrane... not too dissimilar to that of a node of Ranvier... The physiologists went mad over the model, referred to as a “BLM”, an acronym for Bilayer or by some for Black Lipid Membrane. They were as irresistible to play with as soap bubbles.

Indeed, the Rudin group was playing with soap bubbles using equipment purchased from a local toy shop. But scientific experimentation with soap bubbles began with the observations of Robert Hooke (who coined the word “cell” in 1665 to describe the structure of a thin slice of cork tissue observed through a microscope he had constructed), with his observation of “black spots” in soap bubbles and films. Years later, Isaac Newton estimated the blackest soap film

(when light waves reflecting from one layer of soap molecules destructively interfere with light waves reflecting from the second layer of soap molecule) to be about $3\text{--}8 \times 10^{-6}$ in. thick. (Modern measurements give thicknesses between 5 and 9 nm, depending on the soap solution used.)

Origins of the Lipid Bilayer Concept

The recognition of the lipid bilayer as a model for biomembranes dates back to the work of Hugo Fricke, in the 1920s and 1930s, who calculated the thickness of red blood cell (RBC) membranes to be between 3.3 and 11 nm, based on frequency-dependent measurements of the impedance of cell suspensions. Modern measurements on experimental bilayer lipid membranes (BLMs) and biomembranes confirm Fricke’s estimation of the thickness of the plasma membrane (Tien & Ottova, 2000).

In his 1917 studies of the molecular organization of fatty acids at the air–water interface, Irving Langmuir had demonstrated that a simple trough apparatus could provide the data to estimate the dimensions of a molecule. Evert Gorter and F. Grendel (respectively, a pediatrician and a chemist) used Langmuir’s trough to determine the area occupied by lipids extracted from red blood cell (from human, pig, or rat sources) “ghosts” (empty membrane sacs) and found that there was enough lipid to form a layer two molecules thick over the whole cell surface. In other words

$$\frac{\text{surface area occupied (from monolayer experiment)}}{\text{surface area of red blood cell}} \approx 2. \quad (1)$$

Thus, Gorter and Grendel suggested that the plasma membrane of red blood cells may be thought of as a lipid bilayer, with the polar (hydrophilic) head groups oriented outward.

Experimental Realization

The structure of black soap films led to the realization by Rudin and his co-workers in 1960 that a soap film in its final stages of thinning has a structure composed of two fatty acid monolayers sandwiching an aqueous solution as follows:

air | monolayer | soap solution | monolayer | air.

With the above background in mind, Rudin et al. simply proceeded to make a BLM under an aqueous solution, which may be represented as follows:

aqueous solution | BLM | aqueous solution.

Their effort was successful (Tien & Ottova, 2001, p. 86). Rudin and his colleagues showed that a

BLM formed from brain extracts and separating two aqueous solutions was self-sealing to punctures, with many physical and chemical properties similar to those of biomembranes. Upon modification with a certain compound called excitability-inducing molecule (EIM), this otherwise electrically inert structure became excitable, displaying characteristic features similar to those of action potentials of the nerve membrane.

By the end of the early 1970s, it had been determined that an unmodified bilayer lipid membrane separating two similar aqueous solutions is about 5 nm thick and is in a liquid-crystalline state with the following electrical properties: membrane potential ($E_m \approx 0$), membrane resistivity ($R_m \approx 10^9 \Omega \text{ cm}$), membrane capacitance ($C_m \approx 0.5\text{--}1 \mu\text{F cm}^{-2}$), and dielectric breakdown ($V_b > 250,000 \text{ V/cm}$). In spite of its very low dielectric constant ($\epsilon \approx 2\text{--}7$), this liquid-crystalline BLM is surprisingly permeable to water ($8\text{--}24 \mu\text{m/s}$) (Tien & Ottova, 2000).

The Lipid Bilayer Principle

In spite of their variable compositions, the fundamental structural element of all biomembranes is a liquid-crystalline phospholipid bilayer. Thus, the lipid bilayer principle of cell or biological membranes may be summarily stated as follows: all living organisms are made of cells, and every cell is enclosed by a plasma membrane, the indispensable component of which is a lipid bilayer. The key property of lipid bilayer-based cells is that they are separated from the environment by a permeability barrier that allows them to preserve their identity, take up nutrients, and remove waste. This 5 nm thick liquid-crystalline lipid bilayer serves not only as a physical barrier but also as a conduit for transport, a reactor for energy conversion, a transducer for signal processing, a bipolar electrode for redox reactions, or a site for molecular recognition.

The liquid-crystalline lipid bilayer of biomembranes not only provides the physical barrier separating the cytoplasm from its extracellular surroundings, it also separates organelles inside the cell to protect important processes and events. More specifically, the lipid bilayer of cell membrane must prevent its molecules of life (genetic materials and many proteins) from diffusing away. At the same time, the lipid bilayer must keep out foreign molecules that are harmful to the cells. To be viable, the cell must also communicate with the environment to continuously monitor the external conditions and adapt to them. Further, the cell needs to pump in nutrients and release toxic products of its metabolism. How does the cell carry out all of these multi-faceted activities?

A brief answer is that the cell depends on its lipid-proteins-carbohydrate complexes (i.e., glycoproteins,

proteolipids, glycolipids, etc.) embedded in the lipid bilayer to gather information about the environment in various ways. Examples include communication with hundreds of other cells about a variety of vital tasks such as growth, differentiation, and death (apoptosis). Glycoproteins are responsible for regulating the traffic of material to and from the cytoplasmic space. Paradoxically, the intrinsic structure of cell membranes creates a bumpy obstacle to these vital processes of intercellular communication. The cell shields itself behind its lipid bilayer, which is virtually impermeable to all ions (e.g., Na^+ , K^+ , Cl^-) and most polar molecules (except H_2O). This barrier must be overcome, however, for a cell to inform itself of what is happening in the world outside, as well as to carry out vital functions. Thus, over millions and millions of years of evolution, the liquid-crystalline lipid bilayer—besides acting as a physical restraint—has been modified to serve as a conduit for material transport, as a reactor for energy conversion, as a bipolar electrode for redox reactions, as a site for molecular recognition, and other diverse functions such as apoptosis and signal transduction.

Insofar as membrane transport is concerned, cells make use of three approaches: simple diffusion, facilitated diffusion, and active transport. Although simple diffusion is an effective transport mechanism for some substances such as water, the cell must make use of other mechanisms for moving substances in and out of the cell. Facilitated diffusion utilizes membrane channels to allow charged molecules, which otherwise could not diffuse across the lipid bilayer. These channels are especially useful with small ions such as K^+ , Na^+ , and Cl^- . The number of protein channels available limits the rate of facilitated transport, whereas the speed of simple diffusion is controlled by the concentration gradient. Under active transport, the expenditure of energy is necessary to translocate the molecule from one side of the lipid bilayer to the other, in contrast to the concentration gradient. Similar to facilitated diffusion, active transport is limited by either the capacity of membrane channels or the number of carriers present.

Today, ion channels are found ubiquitously. To name a few, they are in the plasma membrane of sperm, bacteria, and higher plants; the sarcoplasmic reticulum of skeletal muscle, nerve membrane, synaptic vesicle membranes of rat cerebral cortex, and the skin of carps. As a weapon of attack, many toxins released by living organisms such as dermonecrotic toxin, hemolysin, brevetoxin, and bee venom are polypeptide-based ion-channel formers. For example, functioning of membrane proteins, in particular, ionic channels, can be modulated by alteration of their arrangement in membranes (e.g., electroporation, Tien & Ottova, 2003).

At the membrane level, most cellular activities involve some kind of lipid bilayer-based

receptor-ligand contact interactions. Outstanding examples among these are ion-sensing, molecular recognition (e.g., antigen-antibody binding and enzyme-substrate interaction), light conversion and detection, gated channels, and active transport. The development of self-assembled bilayer lipid membranes (BLMs and liposomes) has made it possible to investigate directly the electrical properties and transport phenomena across a 5 nm thick biomembrane element separating two aqueous phases. A modified or reconstituted BLM is viewed as a dynamic structure that changes in response to environmental stimuli as a function of time, as described by the so-called dynamic membrane hypothesis. Under this hypothesis, each type of receptor interacts specifically with its own ligand. That is, the so-called G-receptor is usually coupled to a guanosine nucleotide-binding protein that in turn stimulates or inhibits an intracellular, lipid bilayer-bound enzyme. G-protein-linked receptors mediate the cellular responses to a vast variety of signaling molecules, including local mediators, hormones, and neurotransmitters, which are as varied in structure as they are in function. G-protein-linked receptors usually consist of a single polypeptide chain, which threads back and forth across the lipid bilayer up to seven times. The members of this receptor family have a similar amino acid sequence and functional relationship. The binding sites for G-proteins have been reported to be the second and third intracellular loops and the carboxy-terminal tail. The endogenous ligands, such as hormones, neurotransmitters, and exogenous stimulants such as odorants, belonging to this class are important target analytes for biosensor technology Tien & Ottova (2003).

BILLIARDS

In mathematical physics, the singular noun “billiards” denotes a dynamical system corresponding to the inertial motion of a point mass within a region that has a piecewise smooth boundary. The reflections from the boundary are taken to be elastic; that is, the angle of reflection equals the angle of incidence. This model arises naturally in optics, acoustics, and classical and statistical mechanics. In fact, two fundamental models in statistical mechanics, gas of hard spheres (Boltzmann gas) and the Lorentz gas, are billiards. The billiards concept occupies a central position in nonlinear physics because it provides ideal visible models for analysis of dynamical properties leading to classical chaos and an ideal testing ground for the semiclassical analysis of quantum systems.

Billiards models are Hamiltonian systems. Hence, the phase volume is preserved under the dynamics, and the system can be studied in the framework of ergodic theory. In particular, the boundary of the billiard region is supposed to be only piecewise smooth; that is, it consists of smooth components. Therefore, the dynamics of billiards is not defined for orbits that hit singular points of the boundary. However, the phase volume of such orbits equals zero. The dynamics of billiards is completely defined by the shape of its boundary. A smooth component of the boundary is called dispersing, focusing, or neutral if it is convex inward, outward the billiard region, or if it is flat (has zero curvature), respectively. Any billiard orbit is a broken line in its configuration space.

The classical examples of integrable billiards are provided by circular and elliptical boundaries. Configuration spaces of these billiards are foliated by caustics, which are smooth curves (surfaces γ) such that if one link of the billiard orbit is tangent to γ , then every other link of this orbit is tangent to γ . Billiards in a circle has one family of caustics formed by (smaller) concentric circles, while billiards in an ellipse has two families of caustics (confocal ellipses and confocal hyperbolas), which are separated by orbits such that each link intersects a focus of the ellipse. Birkhoff's conjecture (Birkhoff, 1927) claims that among all billiards inside smooth convex curves, only billiards in ellipses are integrable. Berger (1990) has shown that in three dimensions (d), only billiards in ellipsoids produce foliations of a billiard region by smooth convex caustics. However, it does not imply that only billiards in ellipsoids are integrable because if a billiard in $d > 2$ has an invariant hypersurface then this hypersurface does not necessarily consist of

rays tangent to some hypersurface in the configuration space. Using KAM theory, Lazutkin has shown that if a billiards boundary is strictly convex, with a sufficiently smooth curve and its curvature never vanishes; then there exists an uncountable number of smooth caustics in the vicinity of the boundary, and moreover, the phase volume of the orbits tangent to these caustics is positive (Lazutkin, 1991).

An opposite situation occurs when a boundary is everywhere dispersing. Such models were introduced by Sinai (1970), in his seminal paper and they are called Sinai (or dispersing) billiards (Figure 1(a)). Sinai billiards have the strongest chaotic properties; that is, they are ergodic, mixing, have a positive metric entropy, and are Bernoulli systems. If a (narrow) parallel beam of rays is made to fall onto a dispersing boundary, then after reflection it becomes divergent and, therefore, the distance between the rays in this beam increases with time. It is the mechanism of dispersing that generates sensitive dependence on initial conditions (hyperbolicity) and is responsible for strong chaotic properties of dispersing billiards.

On the other hand, focusing boundaries produce the opposite effect. Indeed, a narrow parallel beam of rays after reflection from the focusing boundary becomes convergent; that is, the distance between rays in such a beam decreases with time. Therefore, it has been the general understanding that a dispersing boundary always produces chaotization of the dynamics, while a focusing boundary produces stabilization of the dynamics. However, there exists another mechanism of chaos in billiards (and, in general, in Hamiltonian systems), which is called defocusing (Bunimovich, 1974, 1979). The point is that a narrow parallel beam of rays, after focusing because of reflection from a focusing boundary, may become divergent provided that a free path between two consecutive reflections from the boundary is long enough. Assuming that the time of divergence exceeds (averaged over all orbits) the time of convergence, one obtains chaotic billiards. One of the first, and the most famous, example of such billiards is called a stadium (Figure 1(b)). One obtains a stadium by cutting a circle into two semi-circles and connecting them by two common tangent segments. The length of these segments could be arbitrarily small, which demonstrates that the mechanism of defocusing can work under small deformations of even the integrable (a circle) billiards. Focusing billiards can have as strong chaotic properties as Sinai's billiards do (Bunimovich, 2000).

Figure 1. (a) Sinai billiard. (b) Stadium. (c) Mushroom.

There are no other mechanisms of chaos in billiards. Indeed, billiards in polygons and polyhedrons have zero metric entropy (Boldrighini et al., 1978). Nevertheless, a typical billiard in a polygon is ergodic (Kerckhoff et al., 1986). Because focusing components can form parts of the boundary of integrable as well as chaotic billiards, a natural question is whether there are some restrictions. Two classes of focusing components admissible in chaotic billiards were found (Wojtkowski, 1986; Markarian, 1988). The most general class of such focusing components is formed by absolutely focusing mirrors (AFM) (Bunimovich, 1992). AFMs form a new notion in geometric optics. A mirror γ (or a smooth component of a billiards' boundary) is called absolutely focusing if any narrow parallel beam of rays that falls on γ becomes focused after its last reflection in a series of consecutive reflections from γ . Observe that a mirror is focusing if any parallel beam of rays becomes focused just after the first reflection from this mirror. AFMs can also be characterized in terms of their local properties (Donnay, 1991; Bunimovich, 1992).

Generic Hamiltonian systems are neither integrable nor chaotic. Instead, their phase spaces get divided into KAM-islands and chaotic sea(s). The only clear and clean example of this phenomenon is a billiard in a mushroom (Bunimovich, 2001). The mushroom consists of a semicircular hat sitting on a foot (Figure 1(c)). A mushroom becomes a stadium when the width of the foot equals the width of the hat.

Clearly, the mechanism of dispersing works is higher than two dimensions as well (Sinai, 1970). It is not obvious at all for the mechanism of defocusing because of astigmatism. However, chaotic focusing billiards also do exist in dimension $d \geq 3$ (Bunimovich & Rehacek, 1998). But one pays a price of astigmatism by not allowing the focusing component to be as large as it can be in $d = 2$.

Many properties of classical dynamics of billiards are closely related to the properties of the corresponding quantum problem. Consider the Schrödinger equation with a potential equal to zero inside the billiard region and equal to infinity on the boundary. The eigenfunctions become uniformly distributed over the regions of ergodic billiards for high wave numbers (Shnirelman, 1991). On the contrary, there exist infinite series of eigenfunctions localized in the vicinity of convex caustics of billiards (Lazutkin, 1991).

BINDING ENERGY

When two particles form a bound state under a certain kind of physical interaction, the resulting state has an energy smaller than the sum of the rest energies of the constituent elements of such a bound state. That is why, by definition (or one could say by construction), bound states are ones in which work has to be done to separate the constituents.

The energy that one has to provide (equivalently the work) in order to separate a bound state into its elements is called the binding energy, E_b , and from the above, it can be directly inferred that $E_b > 0$. The equivalent mass to this energy (under the Einstein relation) also bears a name and is called the “mass defect,” $\Delta m = E_b/c^2$, where c is the speed of light.

Examples of binding energy can be easily found among the fundamental forces in nature, such as the gravitational force, the electromagnetic force, and the nuclear force.

Considering an approximately circular (in reality, elliptical) motion of the Earth around the Sun, equating the gravitational force $F_g = GM_s M_e / R^2$ (where G is the gravitational constant, the subscripts s and e denote Sun and Earth, respectively, and R is their relative distance) with the centripetal force $F_c = M_e v^2 / R$, one obtains $v = \sqrt{GM_s / R}$, leading to a kinetic energy $E_k = GM_e M_s / (2R)$, which combined with the potential energy of $E_p = -GM_e M_s / R$, results in a binding energy for the solar system of the form

$$E_b = G \frac{M_e M_s}{2R}. \quad (1)$$

Using the relevant masses for the Earth and Sun and their separation, this quantity can be approximately calculated as $E_b \approx 2.6 \times 10^{33} \text{ J}$ ($\Delta m \approx 2.9 \times 10^{16} \text{ kg}$). However, what actually matters in terms of physical “observability” is the ratio of mass defect to the bound state mass (the closer this ratio is to 1, the greater the possibility of observing the mass defect). In the case of the gravitational system $\Delta M / M_b \approx 1.5 \times 10^{-14}$; hence, the mass defect for the gravitational force will not be observable.

Similar calculations can be performed classically for the hydrogen atom (following the same path, but substituting $G \rightarrow 1/(4\pi\epsilon_0)$, $M_s \rightarrow |q_e|$, and $M_e \rightarrow q_e$, where ϵ_0 is the dielectric constant in a vacuum and q_e is the charge of the electron). In this case, for the electrostatic force,

$$E_b = \frac{1}{2} \frac{q_e^2}{4\pi\epsilon_0 R}. \quad (2)$$

In this case, however, $R \approx 0.53 \times 10^{-10} \text{ m}$ (while in the previous example, it was $\approx 1.5 \times 10^{11} \text{ m}$!). In the case of the hydrogen atom, $E_b \approx 13.6 \text{ eV}$ and $\Delta m \approx 2.5 \times 10^{-35} \text{ kg}$. The ratio $\Delta M / M_b \approx 1.5 \times 10^{-8}$, indicating that in this case also it is not possible to observe the mass defect.

In the case of the nuclear force, however, the ratio of $\Delta M / M_b$ is of order 10^{-3} , and hence it is possible to observe the mass defect. For example, the mass of an α particle consisting of two protons and two neutrons is $6.6447 \times 10^{-27} \text{ kg}$, while the individual masses of these particles add up to $6.6951 \times 10^{-27} \text{ kg}$, resulting in a binding energy of 28.3 MeV and $\Delta M / M_b \approx 0.0075$. In fact, a very common diagram in nuclear physics is the so-called nuclear binding energy curve (see, e.g., <http://hyperphysics.phy-astr.gsu.edu/hbase/nucene/nucbin.html>), which shows the binding energy of various elements as a function of their mass number. In this graph, the larger the E_b , the more stable the element; iron (with atomic number $A = 56$ and binding energy 8.8 MeV/nucleon) is the most stable element. Lighter elements can yield energy by fission, while heavier elements can yield energy by means of fusion, emitting energies in the MeV range.

Binding Energy in Nonlinear Systems

Naturally, bound states of multiple waves can be formed in nonlinear systems. To fix ideas, we will examine such bound states and their corresponding binding energies in the specific context of the well-known sine-Gordon equation. For a detailed exposition of the features and applications of this equation, see Dodd et al. (1982). The sine-Gordon equation in $(1+1)$ dimensions is

$$u_{tt} = u_{xx} - \sin(u). \quad (3)$$

Perhaps, the best-known nonlinear wave solution of this equation consists of the topological soliton (kink), which is of the form (in the static case)

$$u(x) = 4 \tan^{-1}(e^{sx}), \quad (4)$$

$s \in \{-1, 1\}$, where the case of $s = 1$ corresponds to a kink, while $s = -1$ corresponds to an antikink. The energy of such a static kink solution

$$E = \int_{-\infty}^{\infty} dx \left[\frac{1}{2}(u_t^2 + u_x^2) + 1 - \cos(u) \right] \quad (5)$$

can be calculated as $E = 8$.

Another elemental solution of the equation is the breather-like solution of the form

$$u(x, t) = 4 \tan^{-1} \left[\frac{(1 - \omega^2)^{1/2}}{\omega} \frac{\sin(\omega t)}{\cosh((1 - \omega^2)^{1/2} x)} \right]. \quad (6)$$

This exponentially localized in space, periodic in time solution can be considered as a result of a merger of a kink and an antikink. Hence, this is perhaps the simplest example of a bound state in this nonlinear system.

The bound state character of this solution can also be revealed by the expression for its energy. Using expression (6) in Equation (5), we obtain

$$E_{\text{breather}} = 16(1 - \omega^2)^{1/2}. \quad (7)$$

Hence, this energy, for any $\omega \in (0, 1)$ (ω is the frequency of the internal breathing oscillation), is less than the sum of the kink and antikink energies, verifying that the binding energy of such a state is

$$E_b = 16[1 - (1 - \omega^2)^{1/2}]. \quad (8)$$

It is also worthwhile to note that the energy of such a breather excitation varies in the interval $(0, 16)$ depending on its frequency. Hence, there is no threshold for the excitation of such a wave, but even for small amounts of energy, such waveforms will be excited (large frequency/small period ones for small excitation energy).

One can generalize the solution of the form (6) in a periodic breather lattice solution of the sine-Gordon equation in the form (see, e.g., McLachlan, 1994)

$$u(x, t) = 4 \tan^{-1}[a \operatorname{sn}(bt, k^2) \operatorname{dn}(cx, 1 - m^2)], \quad (9)$$

where $\operatorname{sn}(x, k)$ and $\operatorname{dn}(x, k)$ are the Jacobi elliptic functions with modulus k . Here

$$a = \sqrt{\frac{k}{m}}, \quad b = \sqrt{\frac{m}{(m+k)(1+mk)}} \quad \text{and} \\ c = \sqrt{\frac{k}{(m+k)(1+mk)}}.$$

One can then evaluate the energy (per breather) of this infinite periodic breather lattice configuration (for details of the calculation, the interested reader is directed to Kevrekidis et al., 2001) to be

$$E = 16 \sqrt{\frac{k}{(k+m)(1+km)}} E(1 - m^2), \quad (10)$$

where $E(1 - m^2)$ is the complete elliptic integral of the second kind.

Depending on the values of the elliptic moduli, k and m , the expression of Equation (9) represents a lattice of different entities. For $m, k \rightarrow 0$, it corresponds to genuine sine-Gordon breathers. For $k, m \rightarrow 1$, the limit gives the “pseudosphere” solution $u = 4 \tan^{-1}(\tanh \frac{t}{2})$, which resembles a π -kink but in time rather than space (see McLachlan, 1994). On the other hand, the $k \rightarrow$ finite, $m \rightarrow 0$ limit gives the kink-antikink pair solution $4 \tan^{-1}(r \operatorname{sech} x)$. This solution has the character of a kink-antikink pair “breathing” in time.

The above different limits illustrate why Equation (10) is an important result, since it can be used (see below) to obtain the asymptotic interaction between entities such as breathers, pseudospheres, or kink-antikink pairs. When taking the appropriate above limits of expression (10), the leading-order term will be the energy of a single such entity. However, the correction to that will be the (per particle) binding energy in a configuration of multiple such entities (or, as it is often referred to, the energy of interaction between two such entities).

To calculate the breather-breather interaction (their binding energy), we take the limit $m, k \rightarrow 0$, with $k/m = (1 - \omega^2)/\omega^2$, where ω is the breather frequency (see McLachlan, 1994), to obtain

$$E = \left[16 \sqrt{1 - \omega^2} - 8m^2 \frac{(1 - \omega^2)^{3/2}}{\omega^2} + 6m^4 \frac{(1 - \omega^2)^{5/2}}{\omega^4} \right] E(1 - m^2). \quad (11)$$

Hence, the corrections to the (single) breather energy in Equation (11) correspond to the binding energy of the formed breather bound states. Similar expressions can be found for the pseudosphere:

$$E = 4\pi - \frac{\pi}{2}(k-1)^2 + \frac{\pi}{4}(m-1)^2 + \frac{3\pi}{32}(m-1)^2(k-1)^2 \quad (12)$$

(again, 4π is the energy of a single pseudosphere) and for kink-antikink pairs

$$E = \left[16 - 8 \left(k + \frac{1}{k} \right) + 2m^2 \left(2 + 3k^2 + \frac{3}{k^2} \right) \right] \times E(1 - m^2). \quad (13)$$

Similar examples of breather lattices also exist for other equations, such as the well-known Korteweg-de Vries (KdV) equation, and one can again infer breather-breather state binding energies in a similar manner.

In general, one can say that the concept of a bound state for nonlinear evolutionary partial differential equations supporting soliton (or solitary wave) solutions persists in a form very similar to the way it manifests itself for fundamental physical forces and their particle carriers. In the present case, the elements of the bound states are the nonlinear waves proper (a feature reminiscent of the particle-like character of such waves, manifest evidently also in their interactions). In a number of (most often integrable) cases, where the form of the bound state solutions is analytically tractable, the calculation of the bound state energy and of the energy of its constituent elements again provides information, through the difference between the two, for the binding energy (or energy of interaction) of such waves.

BIOLOGICAL EVOLUTION

The term *evolution* defines a process that is driven by internal and/or external forces. In quantum mechanics, an evolution operator conducts change in time. Cosmic evolution in the standard model aims at a consistent description of the process from the “big bang” to the present universe. “Prebiotic evolution” deals with chemical precursors of present-day life and is determined by the conditions at the early Earth, be it in the primordial atmosphere, in the surrounding of volcanic hot springs at the sea floor, or at some other location. “Biological evolution” follows the prebiotic scenario, and it shaped and is still shaping the biosphere on Earth. A temporal change in the biosphere manifests itself as the appearance, alteration, and extinction of biological species. This view was not

generally accepted before Charles Darwin. Influenced by the geologist Charles Lyell and his concept of uniformitarianism, Darwin and the proponents of the theory of evolution suggested that changes in the biosphere occur gradually, continuously, or at least, in small steps. In this aspect, which is not essential for the mechanism of evolution, Darwin’s theory contrasted the view held by the majority of his contemporaries, who assumed constancy of biological species and change exclusively through catastrophic events leading to mass extinction (Ruse, 1979). The opponents of evolutionary thinking, Louis Agassiz, Georges Cuvier, and others, considered species as invariant entities. The remnants of extinct species in the fossil record were interpreted by them as witnesses from earlier worlds destroyed by punctual events, the great deluge, and other catastrophes that wiped out major parts of the organismic world. In society, the concept of evolution was heavily attacked by representatives of the Christian Churches because it was seen to be in conflict with the *Genesis* report in the Bible (Ruse, 2001). During the 20th century, European religious thought has reconciled religious belief and the idea of an evolving biosphere. In North America, the strong opposition of some groups of religious fanatics led to the peculiar development of Creationism, whose claim of being an alternative to the theory of evolution is rejected by the established scientific community (NAS, 1999).

The current theory of biological evolution originated from two epochal contributions by Charles Darwin and Gregor Mendel. Darwin conceived a mechanism for evolutionary change of the biosphere based on variation and selection, and he gathered empirical data providing evidence for the action of natural and artificial selection, the latter exercised in animal breeding and nursery gardens. Darwin’s principle (published in *On The Origin of Species by Natural Selection* in 1859) has two consequences: species adapt to their environments and are related to their ancestors in terms of phylogenies, or branches of an ancestral tree of species. In 1866, Gregor Mendel introduced quantitative statistics into the evaluation of data in biology and performed the first precisely controlled fertilization experiments with plants. He discovered and interpreted correctly the action of genes in determining the properties of organisms. Mendel’s work was considered irrelevant by the evolutionists of the second half of the 19th century and was “rediscovered” around 1900. Only in 1930 were the Darwinian concept of selection and Mendel’s rules of inheritance combined to a common mathematical formalism by the population geneticists Ronald Fisher, John Haldane, and Sewall Wright (for a recent text in population genetics, see Hartl & Clark, 1997). In the 1940s, finally, Darwinian evolution and Mendelian genetics were united in the *Synthetic* or *Neo-Darwinian Theory of Evolution* by the works of the experimental biologists Theodosius

Dobzhansky, Julian Huxley, Ernst Mayr, and others (Mayr, 1997). In the second half of the 20th century, molecular biology put evolutionary theory on firm fundamentals, chemistry and physics. Comparison of genes and, more recently of whole genomes, allows for reconstruction of phylogenies on the basis of nucleotide sequence divergence through mutation (Judson, 1979); the exploration of molecular structures provides insights into the chemistry of present day life; and knowledge of biomolecular properties eventually led to the construction of laboratory systems that allow for observation of evolution of molecules in the test tube (Spiegelman, 1971; Watts & Schwarz, 1997).

Darwinian evolution results from the interplay of variation and selection, both being consequences of reproduction in populations. Variation operates on genomes or genotypes, which are polynucleotide sequences carrying the genetic information, and occurs in two fundamentally different ways: (i) mutation causes local changes in genomic sequences, whereas (ii) recombination exchanges corresponding segments between two genotypes. Selection is based on differences in *fitness* being a property of the phenotype. The phenotype is defined as the union of all, structural as well as dynamic, properties of an individual organism. Unfolding of the phenotype is programmed by the genome; but, at the same time, requires a highly specific environment. In addition, it is influenced by epigenetic factors (epigenetic refers to every nonenvironmental factor that interferes with the development of the organism, except those encoded in the nucleotide sequence of DNA; many epigenetic factors are already understood at the molecular level, and involve specific modifications of genomic DNA). Fitness, in essence, counts the number of fertile descendants reaching the reproductive age. It has two major components: (i) the probability of survival to reproduction, and (ii) the number of viable and fertile offspring.

To illustrate selection in a population of n asexually reproducing phenotypes, we consider a continuous-time model that describes change by a differential equation

$$\frac{dx_i}{dt} = x_i(f_i - \Phi), \quad i = 1, \dots, n$$

with $\Phi(t) = \sum_{j=1}^n f_j x_j = \bar{f}$. (1)

The variables denote the frequencies of reproducing variants: $x_i(t) = N_i(t) / \sum_{j=1}^n N_j(t)$, with $N_i(t)$ counting the number of individuals with phenotype S_i or genotype I_i at time t . (For several genotypes giving rise to the same phenotype, see *neutrality* below.) Fitness values f_i when averaged over the entire population yield the mean fitness expressed by a time-dependent

flux $\Phi(t)$. Frequencies of variants with fitness values above average, $f_i > \Phi$, increase with time, those of below-average variants, $f_i < \Phi$, decrease and as a consequence, the mean fitness increases. The flux $\Phi(t)$ is a nondecreasing function of time and selection continues until all variants, except the fittest, have died out (See also **Fitness landscape**). For two variants, I_0 and I_1 , the solution boils down to

$$\left[\frac{x_1}{x_0} \right] (t) = \left[\frac{x_1}{x_0} \right] (0) \cdot \exp(mt)$$

or

$$\left[\frac{X_1}{X_0} \right]_t = \left[\frac{X_1}{X_0} \right]_0 w^t,$$

where the upper equation refers to continuously varying $x(t)$ and the lower equation refers to population to discrete time variables X_t with synchronized reproduction. The *Malthusian* fitness difference $m = f_1 - f_0$ is related to the *Darwinian* relative fitness $w = (1 + f_1)/(1 + f_2)$ by $m \approx \ln w$ (see Hartl & Clark (1997)). The conditions for selection are $m > 0$ or $w > 1$, respectively. An example is shown in Figure 1.

Sexual reproduction of diploid organisms involves Mendelian genetics (see Figure 2). Every gene (A) comes in two copies, identical or different, which are chosen from a reservoir of variants A_i called alleles. Recombination occurs in the process of reproduction when the two copies are separated and reassembled in pieces through random combination. The differential equation (1) is extended to describe selection in the diploid case in the form of Fisher's selection equation:

$$\begin{aligned} \frac{dx_i}{dt} &= x_i \cdot \left(\sum_{j=1}^n a_{ij} x_j - \Phi \right) \\ &= x_i (\bar{a}_i - \Phi), \quad i = 1, \dots, n \end{aligned} \quad (2)$$

Figure 1. Illustration of selection in populations. The plotted curves represent the frequencies of advantageous mutants I_1 in a population of individuals I_0 with a Malthusian fitness difference of $m = \Delta f = f_1 - f_0 = 0.1, 0.02$, and 0.01 . The population size is $N = 10,000$, and the mutants were initially present in a single copy: $N_1(0) = 1$ or $x_1(0) = 0.0001$.

Figure 2. Mendelian genetics. In sexual reproduction, the two parental genomes are split into pieces and recombined randomly, which means each of the four alleles has a 50 % chance to be incorporated in the genome of an offspring. Mendel's laws are of a statistical nature and hold as mean values in the limit of large numbers of observations. Two cases are shown: (i) the heterozygote unfolds into a phenotype with intermediate properties (gray through blending of black and white), and (ii) the property of one allele (black) is dominant. In the latter case, the other allele (white) is called recessive. Interbreeding of two homozygous individuals (parent generation P) leads to a first offspring generation (F1) of identical heterozygous individuals; the phenotypes in the next (F2) generation show a distribution of 1:2:1 in the intermediate and 1:3 in the dominant/recessive case. Crossing of the (recessive) parent genotype with an F1-individual yields a 1:1 ratio of phenotypes.

with

$$\bar{a}_i = \sum_{j=1}^n a_{ij} x_j,$$

$$\Phi(t) = \bar{a} = \sum_{i=1}^n \bar{a}_i x_i = \sum_{i=1}^n \sum_{j=1}^n a_{ij} x_i x_j.$$

The variables refer to alleles A_j rather than to whole genomes, and the rate coefficient a_{ij} represents the individual fitness values for the combination $A_i A_j$. Fitness is assumed to be independent of the positioning of alleles, $A_i A_j$ or $A_j A_i$, and hence, $a_{ij} = a_{ji}$ holds. The term $\bar{a}_i$ is the population-averaged mean fitness of the allele combinations carrying A_i at least once: $A_i A_j$, $j = 1, \dots, n$. Fisher's fundamental theorem states that the flux $\Phi(t) = \sum_{i=1}^n \bar{a}_i x_i = \bar{a}$ is a nondecreasing function of time, but the outcome of selection need not be unique as optimization might end in a local optimum of Φ (See also **Fitness landscape**). For example, in the two-allele case, inferiority of the heterozygote $A_1 A_2$, $a_{12} < \min\{a_{11}, a_{22}\}$, results in bistability since homogenous populations of either homozygote, $A_1 A_1$ or $A_2 A_2$, represent stable equilib-

rium points. Then, the initial conditions determine the outcome of selection.

The optimization principle is not universally valid: when mutation is included or when more complex cases of recombination are considered, optimization of mean fitness is restricted to certain ranges of initial conditions, whereas different behavior is observed for other starting values. Still, optimization remains an important heuristic in evolution as it is frequently observed.

Innovation is introduced into genes by mutation consisting of a local change in the sequence of nucleotides resulting from an imperfect replication of genetic information or externally caused damage. Two scenarios are distinguished: (i) rare mutation treated by conventional population genetics and typically occurring with multicellular organisms and most bacteria, and (ii) frequent mutation handled by quasispecies theory (Eigen, 1971; Eigen & Schuster, 1977) and determining evolution of viruses. Higher mutation rates are often advantageous because they allow for adaptation, but there exists an error threshold of replication beyond which inheritance breaks down because too many mutations destroy the genetic message. RNA viruses are under a strong selection constraint by the host and their mutation rates are close to the error threshold.

The idea that genotypes and phenotypes are related one-to-one turned out to be wrong. Molecular genetics revealed a high degree of *neutrality* (Kimura, 1983): many different genotypes give rise to the same phenotype. Advantageous mutations are rare; deleterious mutations are eliminated by selection thus leaving a majority of observed changes in the genomes to result from neutral mutations. Neutrality gives rise to random drift of populations in genotype space, which was also found to be important for the mechanism of evolution since it allows populations to escape from minor local fitness optima or evolutionary traps (Schuster, 1996) and Schuster in Crutchfield & Schuster, 2003). Random drift leads to an almost constant mutation rate per year and nucleotide independent of the species being tantamount to a *molecular clock of evolution*. This clock is used for dating in the reconstruction of phylogenies from comparison of present-day genome sequences. Molecular clock dates yield substantially longer time spans compared with those from the fossil record. The discrepancy seems to be reconcilable because paleontological datings are too young and molecular clock datings are too old by systematic errors (Benton & Ayala, 2003).

The Darwinian mechanism is powerful because it makes no reference to the specific nature of the reproducing entities. Therefore, it is likewise valid for molecules, viruses, bacteria, or higher organisms. Selection based on the Darwinian principle is observed in many disciplines outside biology, for example, in

physics and chemistry, in economics, and in the social sciences.

Since its introduction, the theory of evolution has undergone changes and modifications. The rejection of catastrophic events as an important source of change in the history of life on Earth was a political issue rather than one based on scientific data. Geological evidence for fallings of large meteorites as well as major floods is now available, and such events wiped out substantial parts of the biosphere. The paleontological record reflects the interplay between continuous evolution and external influences, which resulted in epochs of gradual development interrupted by punctuated events. Interestingly, evolution of bacteria or molecules under constant conditions also showed punctuation without external triggers: populations "wait" during quasistationary periods for rare mutations that initiate fast periods of change.

Still, there are open problems in current evolutionary theory. Recent sequence data challenge the idea of a tree of life. Although animal phylogeny appears to be on a firm basis, there are problems with the reconstruction of a tree-like history of plant species. Prokaryote evolution cannot be cast into a tree: archbacteria and eubacteria exchange genetic information across species and kingdoms. Such horizontal gene transfer occurs frequently and obscures the descentance of species. Darwinian evolution, although successful in describing the mechanisms of optimization and adaptations of species, is unable to provide explanations for the major evolutionary transitions that lead from one hierarchical level of life to the next higher forms (Maynard Smith & Szathmáry, 1995; Schuster, 1996). Examples of such transitions are the origin of the genetic code; the transition from the prokaryotic to the eukaryotic cell; the transition from unicellular organisms to multicellular plants, fungi, and animals; the transition from solitary animals to animal societies; and eventually the transition to man and human societies. Common to all these transitions is the integration of individual competitors as cooperating elements into a novel functional unit. Simple model mechanisms have been proposed that can explain cooperation of competitors (see, e.g., the hypercycle Eigen & Schuster, 1978), but no real solution to the problem has been found yet.

BIOMOLECULAR SOLITONS

Biological molecules are complex systems that evolve in an ever-changing environment and nevertheless exhibit a remarkable stability of their functions. This feature, which is reminiscent of the exceptional stability of solitons in the presence of perturbations, is perhaps what led to suggestions that solitons could have a role in some biological functions. Beyond this analogy, there are more solid arguments to consider the role of nonlinearity in biological molecules. They are very large atomic assemblies performing their function through large conformational changes, which have a cooperative character because they involve many atoms moving in a coherent manner, and are highly nonlinear due to their amplitude of motion, which is much larger than the standard thermal motions observed in small molecules. Additional nonlinearities can originate from the coupling of different degrees of freedom, as proposed for proteins. Dispersion, necessary to balance the effect of nonlinearity in order to obtain soliton-like excitations, is introduced by the discreteness of the molecular lattice, which behaves in a manner different from a continuous medium.

Besides conformational changes involved in many biological functions, issues important for biological

molecules are energy transport and storage, and charge transport. Nonlinear excitations have been proposed as possible contributors to these phenomena, in the two main classes of biological molecules: nucleic acids and proteins (Peyrard, 1995).

Following Erwin Schrödinger in his prophetic book *What Is Life?* (Schrödinger, 1944), the nucleic acid DNA can be viewed as an "aperiodic crystal." The static structure of DNA is a fairly regular pile of flat base pairs, linked by hydrogen bonds and connected by sugar-phosphate strands that form a double helix (Calladine & Drew, 1997). The lack of periodicity occurs because the base pairs can be either A-T (adenine-thymine) or G-C (guanine-cytosine), their sequence defining the genetic code. The static picture that emerges from crystallographic data has little to do with actual DNA in a living cell. The genetic code, buried in the double helix, would not be accessible if DNA were not a highly dynamical structure. Biologists have observed the "breathing of DNA," which is a fluctuational opening in which one or a few base pairs open temporarily. These motions are probed experimentally by monitoring deuterium-hydrogen exchange, based on the assumption that the imino-protons that bind the bases can only be exchanged for open base pairs. DNA double helix is also opened by enzymes during the transcription of a gene, that is, the reading of the genetic code.

This phenomenon is complex, but there are related experimental observations that are more amenable to physical analysis, on the thermal denaturation of DNA. When the double helix is heated, one first observes local openings over a few to a few tens of base pairs. These grow and invade the whole molecule, leading to a thermal separation of the two strands, which can be monitored by measuring the UV absorbance of the molecule, which is highly sensitive to the disturbance of the base stacking. This "DNA melting"—which appears as a phase transition in one dimension—poses challenging questions because, in order to cause the local openings, one has to break many hydrogen bonds between the bases, which requires the localization of a large amount of thermal energy in a small region of the molecule. Nonlinear effects could be at the origin of this phenomenon.

All these observations led to many investigations and models of the nonlinear dynamics of the DNA molecule. A description at the scale of the individual atoms is not necessary to analyze base-pair openings, so the bases are generally described as rigid objects in these models. The earliest attempt to describe DNA opening in terms of solitons is due to Englander et al. (1980), who viewed it as a cooperative motion involving 10 or more base pairs and propagating as a localized defect along the molecule. This idea was further formalized by Yomosa (1984), and Takeno & Homma (1983), who introduced a coupled base rotator model for the structure and dynamics of DNA. The

Figure 1. (a) Schematic view of the plane base rotator model for DNA. (b) A symmetric open state of the model.

general ideas behind this approach are schematized in Figure 1(a).

Only rotational degrees of freedom of the bases are introduced (denoted by angles χ_n and χ'_n in Figure 1). The pairing of the bases is described by an on-site potential $V(\chi_n, \chi'_n)$, which, in its simplest form is $V(\chi_n, \chi'_n) = A(1 - \cos \chi_n) + A(1 - \cos \chi'_n) + B(1 - \cos \chi_n \cos \chi'_n)$, and the stacking along the molecule is represented by a potential $W(\chi_n, \chi'_n, \chi_{n-1}, \chi'_{n-1}) = S[1 - \cos(\chi_n - \chi_{n-1})] + S[1 - \cos(\chi'_n - \chi'_{n-1})]$, where A, B, S are constants. Adding the kinetic energy of the bases $\frac{1}{2}I(\dot{\chi}_n^2 + \dot{\chi}'_n^2)$, where I is the moment of inertia of the bases around their rotation axis, and summing over n , one obtains the Hamiltonian of the model. Various nonlinear excitations are possible depending on the symmetries of the motion (such as $\chi_n = \chi'_n, \chi_n = -\chi'_n$) and the values of the constants. If the stacking interaction is strong enough, a continuum approximation can be made. This approximation replaces the discrete variables $\chi_n(t)$ by the function $\chi(x, t)$ and finite differences such as $\chi_n - \chi_{n-1}$ by derivatives $a(\partial\chi/\partial x)$, where a is the spacing between the bases and x denotes the continuous coordinate along the helix axis. When $A = 0$, in its simplest form, the model leads to a sine-Gordon equation

$$I \frac{\partial^2 \chi}{\partial t^2} - Sa^2 \frac{\partial^2 \chi}{\partial x^2} + B \sin \chi = 0, \quad (1)$$

which has topological solutions such as the one schematized in Figure 1(b), where the bases undergo a 2π rotation, generating an open state that may slide along the chain.

Models for the rotation of the base pairs have been further refined by Yakushevich (1998) and are discussed in the entry on **DNA solitons**.

Another point of view was chosen later by Dauxois et al. (1993), who were interested in the statistical physics of DNA thermal denaturation. This problem had been studied by Ising models, which simply use a two-state variable equal to 0 or 1 to specify whether a base pair is closed (0) or open (1). Such models cannot describe the intermediate states, but they can be generalized by introducing a real variable $y_n(t)$ that measures the stretching of the hydrogen bonds

in a base pair that is equal to 0 in the equilibrium structure and grows to infinity when the two strands are fully separated. With such a variable, a natural shape of the on-site potential is the Morse potential $V(y_n) = D[\exp(-\alpha y_n) - 1]^2$ (D and α are constants), which has a minimum corresponding to the binding of the two bases in their equilibrium state by the hydrogen bonds, and a plateau at large y_n , which is associated to the vanishing of the pairing force $\partial V/\partial y_n$ when the bases are far apart.

Such a model does not have topological solitons, but its nonlinear dynamics leads to localized oscillatory modes, called breathers, which are approximately described by solitons of the nonlinear Schrödinger equation in the continuum limit and turn into permanently open states at a high temperature (See **Breathers**). These studies have focused attention on the importance of discreteness for nonlinear energy localization. In DNA, the stacking interactions are not very strong, and this is why imino-proton exchange experiments can detect the exchange on one base pair while the neighboring base pairs are not affected. As a result a continuum approximation is very crude. What could appear as a problem because it complicates analytical studies of the nonlinear dynamics turns out to have a far-reaching consequence because it has been shown that discreteness is *crucial* for the existence and formation of nonlinear localized modes (Sievers & Takeno, 1988; MacKay & Aubry, 1994), which correspond to the "breathing" of DNA observed by biologists. It is important to notice that the existence of these nonlinear solutions is not linked to a particular mathematical expression of the potentials. Instead, it is a generic feature of nonlinear lattices having interactions qualitatively similar to those that connect the bases in DNA. Moreover, it has also been shown that thermal fluctuations can self-localize in such lattices so it is likely that related nonlinear excitations could exist in DNA. But discreteness has another consequence. Large-amplitude modes are strongly localized due to their high nonlinearity. Their width becomes of the order of the spacing between the bases and they lose the translational invariance of solitons in continuum media. The image of freely moving solitons has to be corrected by the pinning effect of discreteness, and the translation of the nonlinear excitations in DNA, if it occurs, has to be activated, for instance, by thermal fluctuations.

Proteins are much more complex than DNA because they do not have a quasi-periodic structure, but some of their substructures are nevertheless fairly regular. They are biological polymers composed of amino acids of the general formula

where R is an organic radical that determines the amino acid. These building blocks are linked by a peptide bond that can be viewed as a result of the elimination of a water molecule between consecutive amino acids, leading to the generic formula

A given protein is defined by its sequence of amino acids chosen by 20 possible types and the length of the chain (typically 150–180 residues), but this so-called primary structure does not determine the function that depends on the spatial organization of the residues. Segments of the chain tend to fold into secondary structures having the shape of helices (called α -helices) or sheets (called β -sheets) stabilized by hydrogen bonds formed mainly between the negatively charged $\text{C}=\text{O}$ groups and the positively charged protons linked to the nitrogen atom of a peptide bond. The different components of the secondary structure assemble in the tertiary structure, which is the functional form of the protein.

Proteins perform numerous functions and one of them is the storage and transport of the energy released by the hydrolysis of adenosine-triphosphate (ATP), which plays the role of the fuel necessary for many biological processes, such as muscle contraction. The hydrolysis of a single ATP molecule releases approximately 0.4 eV, which is transmitted to a protein for later use. This raises a puzzling question because, if this energy were distributed among all the degrees of freedom of a protein, each atom would carry such a small amount that the energy would be useless. There must be a mechanism that maintains this energy sufficiently localized, and moreover, as it will not be used at the site where it has been released, it must be transported efficiently within the molecule. Recent experiments at the molecular scale have shown that the hydrolysis of a single ATP molecule can be used for *several* steps of a molecular motor involved in muscle contraction (Kitamura et al., 1999), providing evidence of the temporary storage of the energy.

Attempting to understand these phenomena in 1973, Alexander Davydov noticed that the energy released by ATP hydrolysis almost coincides with 2 quanta of the vibrational energy of the $\text{C}=\text{O}$ bond, which led him to the conclusion that this energy was stored as vibrational energy in the peptide bond (Scott, 1992). He conjectured that it could stay localized through an extrinsic nonlinearity associated with a distortion of the chain of hydrogen bonds that spans the α -helix. The underlying mechanism is similar to the one leading

to the formation of a polaron in solid-state physics (Ashcroft & Mermin, 1976). The vibration of the C=O bond strains the lattice in its vicinity, resulting in slight displacements of the neighboring amino acids. But, as the frequency of the C=O vibration is affected by its interactions with the neighboring atoms, the frequency of the excited C=O bond becomes slightly shifted and no longer coincides with the resonating frequencies of the neighboring C=O bonds, preventing an efficient transfer of energy to the neighboring sites. As a consequence, the energy released by the ATP hydrolysis does not spread along the protein.

Therefore, the basic idea behind the mechanism proposed by Davydov is nonlinear energy localization due to the shift of the frequency of an oscillator when it is excited. For the protein, it is not due to an intrinsic nonlinearity of the C=O bond (as was the case for the Morse potential linking the bases in a pair for DNA), but due to a coupling with another degree of freedom, which is an acoustic mode of the lattice of amino acids connected by hydrogen bonds.

As only a few quanta of the C=O vibrational motion are excited, the theory cannot ignore quantum effects, and in order to go beyond the qualitative picture discussed above, one has to solve the time-dependent Schrödinger equation. Davydov proposed a simple *ansatz* to describe the quantum state of the system. In this simple approximation, the motion of the self-trapped energy packet is described by a discrete form of the nonlinear Schrödinger equation. When one introduces proper parameters for the α -helix, the calculation of the soliton width shows that it is much broader than the lattice spacing, which should allow its motion without pinning by discreteness. As a result, energy transfer by solitons in the α -helix is plausible, but a definitive conclusion about the existence of such solitons is still pending. This is because the role of thermal fluctuations, which could destroy the coherence of the lattice distortion around the excited C=O site and hence the self-trapping, and the extent of quantum effects are hard to evaluate quantitatively (Peyrard, 1995). A direct experimental observation on a protein has not been possible up to now.

These uncertainties prompted physicists and physical chemists to experimentally investigate model systems that are simpler than proteins but, nevertheless, show chemical bonds comparable to the peptide bonds in proteins. Crystalline acetanilide consists of quasi-one-dimensional chains of hydrogen-bonded peptide groups. In the early 1980s, it was recognized by spectroscopic studies that the C=O stretching and N-H stretching bands of crystalline acetanilide exhibit anomalies, and tentative explanations involve self-trapped states similar to the Davydov solitons. These ideas have been confirmed by recent pump-probe experiments (Edler et al., 2002). A direct observation of self-trapping could be achieved, and it appears that the

crystal structure is essential to stabilize the excitation that decays 20 times faster for isolated molecules than for molecules linked by hydrogen bonds in the crystal. Although the lifetime of the self-trapped state (20 ps) is shorter than expected by Davydov, this study supports the original idea of the importance of the coupling with the lattice degrees of freedom. A possible translational motion of the self-trapped state and its possible role for biological functions are still open questions.

The *News and Views* section of the journal *Nature* attests that nonlinear excitations in biomolecules have been the object of strong controversy, ranging from enthusiastic approval (Maddox, 1986, 1989) to harsh criticisms (Frank-Kamenetskii, 1987), which were justified by some of the overstatements by theoreticians. Today, passionate opinions have subsided and experiments at the scale of a single molecule have become feasible, showing us how biomolecules work or take their shape. Thus, it appears likely that while freely moving solitons along DNA or protein α -helices may not exist, nonlinear excitations leading to energy localization or storage, and perhaps transport, could well provide useful clues to understand some of the phenomena occurring in biomolecules.

BJERRUM DEFECTS

Ice is the most common and important member in a class of solids in which the conduction of electricity is carried almost exclusively by protons. Its dc electrical conductivity reaches the level of $10^{-7} \Omega^{-1} \text{ m}^{-1}$, placing ice among the semiconductors. Known protonic semiconductors include disordered forms of solid water and several salt hydrates and gas hydrates. In the case of lithium hydrazinium sulfate ($\text{LiN}_2\text{H}_5\text{SO}_4$), one finds quasi-one-dimensional hydrogen-bonded chains (HBCs) along the *c*-crystallographic axis. Electrical conductivity is three orders of magnitude larger in the *c*-direction (compared with the perpendicular directions), demonstrating that proton conductivity is directly related to the presence of hydrogen bonds. In addition to inorganic crystals, protonic conductivity plays a significant role in biological systems, where it participates in energy transduction and formation of proton pumps. Of particular significance is proton transport across cellular membranes through the use of hydrogen-bonded side-chains of proteins embedded in membrane pores.

As is shown in Figures 1 and 2, protonic conductivity in HBCs takes place through ionic defects and bonding or “Bjerrum” defects (named after Danish physical chemist Niels Bjerrum). Ionic defects are formed by an excess proton (H_3O^+) or a proton vacancy (HO^-), while bonding defects are misfits in the orientations of neighboring atoms resulting in either vacant bonds (L defect) or placing two protons in the same bond (D defect). Bonding defects do not obey the Bernal-Fowler rule of one proton per hydrogen bond for the ideal ice crystal.

When a proton is transported along an HBC through an ionic defect, after the passage of the proton, the chain remains blocked to further proton movement since all chain protons have been moved, say, from the left-hand to the right-hand side of each hydrogen bond. The chain gets unblocked through cooperative rotations, that is, through the passage of a bonding defect. Thus, protons move in an HBC through coordinated ionic and Bjerrum defects, using a mechanism that is also found in hydrogen-bonded protein side chains. Coordinated proton transport in biological macromolecules leads to the formation of proton pumps that channel protons across membranes and, through reversals, produce cyclic motor actions of mechanical nature. Defects in HBCs are topological in nature, with the rotational activation energy being smaller than that of ionic defect energy. The total charge of the topological ionic and bonding defects is not the same; in ice, the ionic defect charge is $e_I = 0.64e$ (e is the proton charge), while the bonding defect charge is $e_B = 0.36e$. Only after a coordinated passage of an ionic and bonding defect is one entire proton charge transferred across the HBC.

A simple one-dimensional cooperative model of an HBC is similar to the Frenkel-Kontorova model but with two alternating barriers modeling bonding and ionic activation energies. The minima separating the barriers correspond to equilibrium positions of protons that interact mutually through dipole-dipole interactions. In equilibrium under this model, there is initially one proton per hydrogen bond; transitions of protons over the large barriers correspond to ionic defects, while bonding defects result from transitions over the smaller barrier. Both classes of defects are modeled through topological solitons. There are two kink solutions corresponding to HO^- and L-bonding defects, while the corresponding antikinks are the H_3O^+ and D-bonding defects, respectively.

This simple model can be made quantitative through the introduction of the one-dimensional Hamiltonian

$$H = \sum_n \left[\frac{p_n^2}{2} + \frac{1}{2}(u_{n+1} - u_n)^2 + \omega V(u_n) \right], \quad (1)$$

where u_n and p_n are the dimensionless displacement from an equilibrium position and momentum, respectively, of the n th hydrogen that is coupled to its nearest

Figure 1. Ionic defects present in a hydrogen bonded chain: (a) negative ionic defect HO^- and (b) positive ionic defect H_3O^+ . Large open circles denote ions, for example, oxygen ions in ice, while small black dots are protons. A hydrogen bond that links two ions contains a covalent part (solid line) that places in equilibrium the proton closer to one of the two oxygens. In the ionic defect region, there is a gradual transition in the equilibrium locations of protons within the hydrogen bonds; this transitional region is modeled through a topological soliton.

Figure 2. Bonding defects in a hydrogen bonded chain: (a) negative bonding defect (L) and (b) positive bonding defect (D). Molecular rotations introduce additional protons or remove protons from the quasi-one-dimensional HBC and produce bonding defects.

neighboring protons through harmonic spring interaction, while ω sets the energy scale. A typical choice for $V(u_n)$, the nonlinear substrate potential that models the ionic and bonding barriers, is

$$V(u_n) = \frac{2}{1 - \alpha^2} \left[\cos\left(\frac{u_n}{2}\right) - \alpha \right]^2. \quad (2)$$

The substrate potential (2) is periodic and (for appropriate values of the parameter α) is doubly periodic with two distinct alternating maxima that separate degenerate minima. In this model, one assumes one proton per unit cell, the latter consisting of the larger ionic barrier with its adjacent minima, one on each side. In the strongly cooperative limit, where neighboring hydrogen displacements do not differ substantially, one obtains for the proton displacement $u(x, t)$ that becomes a function of the continuous space variable x as well as time t the double sine-Gordon partial differential equation:

$$u_{tt} - c^2 u_{xx} + \frac{\omega^2}{1 - \alpha^2} \left[-\sin u + 2\alpha \sin \frac{u}{2} \right] = 0, \quad (3)$$

where c is the speed of sound of the linearized lattice oscillations. This sine-Gordon model has as solutions two sets of soliton kinks as well as their corresponding antikinks representing L-Bjerrum (kink I), D-Bjerrum (antikink I), HO^- ionic (kink II) and H_3O^+ (antikink II). More complex nonlinear models can be constructed that also include an acoustic interaction between neighboring ions as well as coupling of protons with ions. In these cases, one obtains two component solitons where the defects in the proton sublattice are topological solitons that induce a polaronic-like deformation in the ionic lattice. This more complex defect can travel along an HBC when an external electric field is applied in the system. Numerical

simulations demonstrate that these nonlinear defects do indeed encompass some of the basic dynamical properties of the ionic and bonding defects found in hydrogen-bonded networks.

BLACK HOLES

A massive body like the Earth is characterized by an “escape velocity,” which is the speed that a moving particle must have on leaving the surface of the body to leave the attraction of gravity. Consider a bullet at the surface of the Earth that is moving upward with a speed of 11.2 km/s and neglect atmospheric friction. Such a bullet will just escape Earth’s gravitational field by exchanging its kinetic energy for the potential energy of the gravitational field. If the mass of the Earth were compressed into a smaller radius, this escape velocity would be larger, because the gravitational energy to be overcome by the kinetic energy of the bullet would be larger.

In 1916, Karl Schwarzschild used Einstein's gravitational field equations to show that if a body of mass m is compressed to a radius

$$r_s = \frac{2Gm}{c^2}, \quad (1)$$

where G is the gravitational constant, then an object traveling at the speed of light c will be unable to escape the influence of gravity (Schwarzschild, 1916). For a body having the mass of the Earth, this "Schwarzschild radius" is about 1 cm, and for the Sun, it is about 3 km. Interestingly, Schwarzschild's idea was first suggested in the 18th century (Mitchell, 1783; Laplace, 1796).

The term "black hole" was coined by John Archibald Wheeler in 1967 to denote a cosmic object with its mass concentrated within the Schwarzschild radius. Neither particles nor light can overcome gravitational attraction and travel outside the sphere of radius r_s . Interestingly, Stephen Hawking (1974) has shown that—due to quantum fluctuations—a black hole should radiate as a black body with the temperature

$$T = \frac{hc}{4\pi k r_s}, \quad (2)$$

where k and h are, respectively, the Boltzmann and Planck constants. Indirect evidence for black holes is provided by the fact that there do not exist stable cold stars with masses larger than about three Sun masses. Under its own gravitational field, according to theory, such a star should collapse into a black hole. In 1931, Subrahmanyan Chandrasekhar was the first to conclude that above some critical mass of white dwarfs, the equation of state (of a quantum relativistic gas of degenerate Fermi particles) is too weak to counter the gravitational forces, leading to the formation of black holes. Both Lev Landau (1932) and Arthur Eddington (1924) rejected this implication of relativistic quantum mechanics rather than accept the possibility of black holes. Albert Einstein also concluded that Schwarzschild singularities do not exist in the real world (Einstein, 1939).

In 1939, however, J. Robert Oppenheimer and his colleagues used general relativity (rather than Newtonian gravity) to show that when all thermonuclear sources of energy are exhausted (with no further outward pressure due to radiation), a sufficiently heavy star will continue to contract indefinitely, never reaching equilibrium (Oppenheimer & Volkoff, 1939; Oppenheimer & Snyder, 1939). Oppenheimer et al. further noted that if one considers stellar collapse from the inside, a stationary observer sees the stellar surface moving inward to the Schwarzschild sphere and finally sees the surface freeze as it nears the Schwarzschild sphere. Moreover, they showed that observers who move inward with the collapsing matter do not observe such freezing; these observers could cross the critical surface ("event horizon") after a finite time on their own

clocks, after which they have no possibility of sending a signal that could be detected by an observer located outside the collapsing matter.

Recently, the scientific history of black holes has been characterized by a rapid growth of observational, theoretical, and mathematical studies, in which the discovery of such compact objects becomes the main purpose (Thorne et al., 1986). Currently, the most important classes are black holes of stellar masses (about 3–10 solar masses) and super-massive black holes. The most convincing candidates for stellar black holes are binary X-ray sources, one component of which is an ordinary star and the other component is a black hole or neutron star (Novikov & Zeldovich, 1966). Estimates of the masses of compact objects in these systems are essentially greater than three solar masses, and one example of such a system is Cygnus X-1 (V 1357 Cyg). The present number of systems mentioned as possible candidates for black holes with stellar masses is about 20, all of which are X-ray sources in binary systems (Novikov & Frolov, 2001). In the case of super-massive black holes and nuclei of Seyfert galaxies, interpretations of the observable effects using the black hole theory seem the most simple and natural; for example, Galaxy M 31 is a black hole candidate having a mass of about 3×10^7 the Sun's mass (Novikov & Frolov, 2001).

Presently, the concept of black holes continues to be confirmed by direct observations and is used to explain observable astronomical effects related to exceptionally strong emission of energy. Thus, it is expected that in the future new astronomical objects will be detected near black holes, and new physical phenomena will be discovered that can be interpreted using the black hole concept. Along these lines, it is interesting to note recent work in which concepts from thermodynamics and information theory (such as temperature and entropy) are connected with black holes based on Hawking's ideas (Markov, 1965; Hawking, 1977). Also of interest are "artificial black holes," which do not compress a large amount of mass into a small volume, but reduce the speed of light in a moving medium to less than the speed of the medium, thereby creating an event horizon (Leonhardt, 2001).

BORN-INFELD EQUATIONS

Classical linear vacuum electrodynamics with point massive charged particles has two limiting properties: the electromagnetic energy of a point particle field is infinity, and a Lorentz force must be postulated to describe interactions between point particles

and an electromagnetic field. Nonlinear vacuum electrodynamics can be free of these imperfections.

Gustav Mie (1912–1913) considered a nonlinear electrodynamics model in the framework of his “Fundamental unified theory of matter.” In this theory the electron is represented by a nonsingular solution with a finite electromagnetic energy, but Mie’s field equations are noninvariant under the gauge transformation for an electromagnetic four-potential (addition of the four-gradient of an arbitrary scalar function).

Max Born (1934) considered a nonlinear electrodynamics model that is invariant under the gauge transformation. A stationary electron in this model is represented by an electrostatic field configuration that is everywhere finite, in contrast to the case of linear electrodynamics when the electron’s field is infinite at the singular point (see Figure 1). The central point in Born’s electron is also singular because there is a discontinuity of electrical field at this point (hedgehog singularity). The full electromagnetic energy of this electron’s field configuration is finite.

Born and Leopold Infeld (1934) then considered a more general nonlinear electrodynamics model, which has the same solution associated with the electron. Called Born–Infeld electrodynamics, this model is based on the Born–Infeld equations, which have the form of Maxwell’s equations, including electrical and magnetic field strengths $\mathbf{E}$, $\mathbf{H}$, and inductions $\mathbf{D}$, $\mathbf{B}$ with nonlinear constitutive relations $\mathbf{D} = \mathbf{D}(\mathbf{E}, \mathbf{B})$, $\mathbf{H} = \mathbf{H}(\mathbf{E}, \mathbf{B})$ of a special kind. For inertial reference frames and in the region outside of field singularities, these equations are

$$\left\{ \begin{array}{l} \operatorname{div} \mathbf{B} = 0, \\ \frac{1}{c} \frac{\partial \mathbf{B}}{\partial t} + \operatorname{curl} \mathbf{E} = 0, \\ \operatorname{div} \mathbf{D} = 0, \\ \frac{1}{c} \frac{\partial \mathbf{D}}{\partial t} - \operatorname{curl} \mathbf{H} = 0, \end{array} \right. \quad (1)$$

where

$$\begin{aligned} \mathbf{D} &= \frac{1}{\mathcal{L}} (\mathbf{E} + \chi^2 \mathcal{J} \mathbf{B}), \\ \mathbf{H} &= \frac{1}{\mathcal{L}} (\mathbf{B} - \chi^2 \mathcal{J} \mathbf{E}), \end{aligned} \quad (2)$$

$$\begin{aligned} \mathcal{L} &\equiv \sqrt{|1 - \chi^2 \mathcal{I} - \chi^4 \mathcal{J}^2|}, \\ \mathcal{I} &= \mathbf{E} \cdot \mathbf{E} - \mathbf{B} \cdot \mathbf{B}, \quad \mathcal{J} = \mathbf{E} \cdot \mathbf{B}. \end{aligned} \quad (3)$$

Relations (2) can be resolved for $\mathbf{E}$ and $\mathbf{H}$:

$$\begin{aligned} \mathbf{E} &= \frac{1}{\mathcal{H}} (\mathbf{D} - \chi^2 \mathcal{P} \times \mathbf{B}), \\ \mathbf{H} &= \frac{1}{\mathcal{H}} (\mathbf{B} + \chi^2 \mathcal{P} \times \mathbf{D}), \end{aligned} \quad (4)$$

Figure 1. Radial components of electrical field for Born's electron and purely Coulomb field (dashed).

where $\mathcal{H} = \sqrt{1 + \chi^2 (\mathbf{D}^2 + \mathbf{B}^2) + \chi^4 \mathcal{P}^2}$, $\mathcal{P} \equiv \mathbf{D} \times \mathbf{B}$. Using relations (4) for Eq. (1), the fields $\mathbf{D}$ and $\mathbf{B}$ are unknown.

The symmetrical energy-momentum tensor for Born-Infeld equations has the following components:

$$\begin{aligned} T^{00} &= \frac{1}{4\pi\chi^2} (\mathcal{H} - 1), \quad T^{0i} = \frac{1}{4\pi} \mathcal{P}^i, \\ T^{ij} &= \frac{1}{4\pi} \left\{ \delta^{ij} [\mathbf{D} \cdot \mathbf{E} + \mathbf{B} \cdot \mathbf{H} - \chi^{-2} (\mathcal{H} - 1)] \right. \\ &\quad \left. - (D^i E^j + B^i H^j) \right\}. \end{aligned} \quad (5)$$

In spherical coordinates, the field of Born's static electron solution may have only radial components

$$D_r = \frac{e}{r^2}, \quad E_r = \frac{e}{\sqrt{\bar{r}^4 + r^4}}, \quad (6)$$

where e is the electron's charge and $\bar{r} \equiv \sqrt{|\chi|e}$. At the point $r=0$, the electrical field has the maximum absolute value

$$|E_r(0)| = \frac{|e|}{\bar{r}^2} = \frac{1}{\chi}, \quad (7)$$

which Born and Infeld called the absolute field constant.

The energy of field configuration (6) is

$$m = \int T^{00} dV = \frac{2}{3} \beta \frac{\bar{r}^3}{\chi^2}, \quad (8)$$

where the volume integral is calculated over the whole space, and

$$\beta \equiv \int_0^\infty \frac{dr}{\sqrt{1+r^4}} = \frac{[\Gamma(\frac{1}{4})]^2}{4\sqrt{\pi}} \approx 1.8541. \quad (9)$$

In view of the definition for $\bar{r}$ below (6), Equation (8) yields

$$\bar{r} = \frac{2}{3} \beta \frac{e^2}{m}. \quad (10)$$

Considering m as the mass of electron and using (7), Born & Infeld (1934) estimated the absolute field constant $\chi^{-1} \approx 3 \times 10^{20}$ V/m. Later, Born & Schrödinger (1935) gave a new estimate (two orders of

magnitude less) based on some considerations taking into account the spin of the electron. (Of course, such estimates may be corrected with more detailed models.)

An electrically charged solution of the Born-Infeld equations can be generalized to a solution with the singularity having both electrical and magnetic charges (Chernitskii, 1999). A corresponding hypothetical particle is called a dyon (Schwinger, 1969). Nonzero (radial) components of fields for this solution have the form

$$\begin{aligned} D_r &= \frac{\mathcal{E}}{r^2}, \quad E_r = \frac{\mathcal{E}}{\sqrt{\bar{r}^4 + r^4}}, \\ B_r &= \frac{\mathcal{C}}{r^2}, \quad H_r = \frac{\mathcal{C}}{\sqrt{\bar{r}^4 + r^4}}, \end{aligned} \quad (11)$$

where $\mathcal{E}$ is the electric charge and $\mathcal{C}$ is the magnetic one; $\bar{r} \equiv [\chi^2 (\mathcal{E}^2 + \mathcal{C}^2)]^{1/4}$. The energy of this solution is given by Equation (8) with this definition for $\bar{r}$. It should be noted that space components of electromagnetic potential for the static dyon solution have a line singularity.

A generalized Lorentz force appears when a small, almost constant field $\bar{\mathbf{D}}$, $\bar{\mathbf{B}}$ is considered in addition to the moving dyon solution. The sum of the field $\bar{\mathbf{D}}$, $\bar{\mathbf{B}}$ and the field of the dyon with varying velocity is taken as an initial approximation to some exact solution. Conservation of total momentum gives the following trajectory equation (Chernitskii, 1999):

$$\begin{aligned} m \frac{d}{dt} \frac{\mathbf{v}}{\sqrt{1-v^2}} &= \mathcal{E} (\bar{\mathbf{D}} + \mathbf{v} \times \bar{\mathbf{B}}) \\ &\quad + \mathcal{C} (\bar{\mathbf{B}} - \mathbf{v} \times \bar{\mathbf{D}}), \end{aligned} \quad (12)$$

where $\mathbf{v}$ is the velocity of the dyon, and m is the energy for static dyon defined by (8).

A solution with two dyon singularities (called a bidyon) having equal electric ($\mathcal{E} = e/2$) and opposite magnetic charges can be considered as a model for a charged particle with spin (Chernitskii, 1999). Such a solution has both angular momentum and magnetic moment.

A plane electromagnetic wave with arbitrary polarization and form in the direction of propagation (without coordinate dependence in a perpendicular plane) is an exact solution to the Born-Infeld equations. The simplest case assumes one nonzero component of the vector potential ($A_y \equiv \phi(t, x)$), whereupon Equations (1) reduce to the linearly polarized plane wave equation

$$\begin{aligned} (1 + \chi^2 \phi_x^2) \phi_{tt} - \chi^2 2 \phi_x \phi_t \phi_{xt} \\ - (c^2 - \chi^2 \phi_t^2) \phi_{xx} = 0 \end{aligned} \quad (13)$$

with indices indicating partial derivatives. Sometimes called the Born-Infeld equation, Equation (13) has solutions $\phi = \zeta(x^1 - x^0)$ and $\phi = \zeta(x^1 + x^0)$, where $\zeta(x)$ is an arbitrary function (Whitham, 1974). Solutions

comprising two interacting waves propagating in opposite directions are obtained via a hodograph transform (Whitham, 1974). Brunelli & Ashok (1998) have found a Lax representation for solutions of this equation.

A solution to the Born–Infeld equations, which is the sum of two circularly polarized waves propagating in different directions, was obtained by Erwin Schrödinger (1943).

Equations (1) with relations (2) have an interesting characteristic equation (Chernitskii, 1998)

$$g^{\mu\nu} \frac{\partial \Phi}{\partial x^\mu} \frac{\partial \Phi}{\partial x^\nu} = 0, \quad g^{\mu\nu} \equiv g^{\mu\nu} - 4\pi \chi^2 T^{\mu\nu}, \quad (14)$$

where $\Phi(x^\mu) = 0$ is an equation of the characteristic surface and $T^{\mu\nu}$ are defined by (5). This form for $g^{\mu\nu}$, including in addition the energy-momentum tensor, is special for Born–Infeld equations.

The Born–Infeld model also appears in the quantized string theory (Fradkin & Tseytlin, 1985) and in Einstein’s unified field theory with a nonsymmetrical metric (Chernikov & Shavokhina, 1986). In general, this nonlinear electrodynamics model is connected with ideas of space-time geometrization and general relativity (see Eddington, 1924; Chernitskii, 2002).

BOSE-EINSTEIN CONDENSATION

Bose–Einstein condensation (BEC) is the occupation of a single quantum state by a large number of identical particles, which implies that the particles are bosons, satisfying Bose–Einstein statistics and allowing for many particles to pile up in the same quantum state. This is in contrast to fermions, satisfying Fermi–Dirac statistics, for which the Pauli exclusion principle forbids the occupation of any single quantum state by more than one particle.

The role of quantum correlations caused by Bose–Einstein statistics is crucial for the occurrence of BEC. These statistics were advanced by Satyendranath Bose (1924) for photons, having zero mass, and generalized by Albert Einstein (1924) to particles with nonzero masses. Einstein (1925) also described the phenomenon of condensation in ideal gases. The possibility of BEC in weakly nonideal gases was theoretically demonstrated by Nikolai Bogolubov (1947). The wave function of Bose-condensed particles in dilute gases satisfies the Gross–Pitaevskii equation, suggested by Gross (1961) and Pitaevskii (1961). Its mathematical structure is that of the nonlinear Schrödinger equation. Experimental evidence of BEC in weakly interacting confined gases was achieved 70 years after Einstein’s prediction, almost simultaneously, by three experimental groups (Anderson et al., 1995; Bradley et al., 1995; Davis et al., 1995).

To say that many particles are in the same quantum state implies that these particles display state coherence, a particular example of coherence phenomena requiring the particles to be strongly correlated with each other. The necessary conditions may be qualitatively understood by applying the de Broglie duality arguments to an ensemble of atoms in thermodynamic equilibrium at temperature T . Then the thermal energy of an atom is given by $k_B T$, where k_B is the Boltzmann constant. This energy defines the thermal wavelength

$$\lambda_T \equiv \sqrt{2\pi\hbar^2/m_0 k_B T} \quad (1)$$

for an atom of mass m_0 , with $\hbar$ being the Planck constant. Thus, an atom can be associated with a matter wave characterized by the wavelength (λ_T). Atoms become correlated with each other when their related waves overlap, which requires that the wavelength be larger than the mean interatomic distance, $\lambda_T > a$. The average atomic density $\rho \equiv N/V$ for N atoms in

volume V is related to the mean distance a through the equality $\rho a^3 = 1$. Hence, condition $\lambda_T > a$ may be rewritten as $\rho \lambda_T^3 > 1$. With the thermal wavelength (1), this yields the inequality

$$T < \frac{2\pi \hbar^2}{m_0 k_B} \rho^{2/3}, \quad (2)$$

which implies that state coherence may develop if the temperature is sufficiently low or the density of particles is sufficiently high.

An accurate description of BEC for an ideal gas is based on the Bose–Einstein distribution

$$n(\mathbf{p}) = \left[\exp \left(\frac{\varepsilon_{\mathbf{p}} - \mu}{k_B T} \right) - 1 \right]^{-1}, \quad (3)$$

describing the density of particles with a single-particle energy $\varepsilon_{\mathbf{p}} = p^2/2m_0$ for a momentum $\mathbf{p}$ and with a chemical potential μ . The latter is defined from the condition $N = \sum_{\mathbf{p}} n(\mathbf{p})$ for the total number of particles. Assuming the thermodynamic limit

$$N \rightarrow \infty, \quad V \rightarrow \infty, \quad \frac{N}{V} \rightarrow \text{const}$$

allows the replacement of summation over $\mathbf{p}$ by integration. Then, the fraction of particles, condensing to the state with $\mathbf{p} = 0$ is

$$n_0 \equiv \frac{N_0}{N} = 1 - \left(\frac{T}{T_c} \right)^{3/2} \quad (4)$$

below the condensation temperature

$$T_c = \frac{2\pi \hbar^2 \rho^{2/3}}{m_0 k_B \zeta^{2/3}}, \quad (5)$$

where $\zeta \approx 2.612$. Above the critical temperature (5), $n_0 = 0$. The latter is about half of the right-hand side of inequality (2).

The condensate fraction (4) is derived for an ideal (noninteracting) Bose gas. A weakly nonideal (weakly interacting) Bose gas also displays Bose–Einstein condensation, although particle interactions deplete the condensate so that at zero temperature the condensate fraction is smaller than unity ($n_0 < 1$). A system is called weakly interacting if the characteristic interaction radius r_{int} is much shorter than the mean interparticle distance ($r_{\text{int}} \ll a$). This inequality can be rewritten as $\rho r_{\text{int}}^3 \ll 1$, and such a system is termed dilute.

Superfluid liquids, such as liquid ^4He , are far from being dilute, but it is commonly believed that the phenomenon of superfluidity is somehow connected with BEC. Although an explicit relation between the superfluid and condensate fractions is not known, theoretical calculations and experimental observations for superfluid helium estimate the condensate fraction at $T = 0$ as $n_0 \approx 0.1$.

A strongly correlated pair of fermions can be treated approximately as a boson, allowing superfluidity in

liquid ^3He to be interpreted as the condensation of coupled fermions. Similarly, superconductivity is often compared with the condensation of the Cooper pairs that are formed by correlated electrons or holes. One should understand, however, that the superconductivity of fermions is analogous to but not identical to BEC of bosons.

An ideal object for the experimental observation of BEC is a dilute atomic Bose gas confined in a trap and cooled down to temperatures satisfying condition (2). Such experiments with different atomic gases have been recently realized, BEC has been explicitly observed, and a variety of its features have been carefully investigated. It has been demonstrated that the system of Bose-condensed atoms displays a high level of state coherence.

There exist different types of traps (single- and double-well), magnetic, optical, and their combinations, which make it possible to confine atoms for sufficiently long times of up to 100s. Using a standing wave of laser light, multi-well periodic effective potentials called optical lattices have been obtained, which have allowed the demonstration of a number of interesting effects, including Bloch oscillations, Landau–Zener tunneling, Josephson current, Wannier–Stark ladders, Bragg diffraction, and so on.

Displaying a high level of state coherence, an ensemble of Bose-condensed atoms forms a matter wave that is analogous to a coherent electromagnetic wave from a laser. Therefore, a device emitting a coherent beam of Bose atoms is called an atom laser.

The realization of BEC of dilute trapped gases is important for several reasons. First, this demonstrated the phenomenon predicted by Einstein in the 1920s. Note that a direct observation of BEC in superfluid helium—despite enormous experimental efforts—has never been achieved. Second, dilute atomic gases are simple statistical systems that can serve as a touchstone for testing different theoretical approaches. Finally, Bose-condensed trapped gases display a variety of interesting properties that promise diverse practical applications.

BOUNDARY LAYERS

The Navier–Stokes system is the basic mathematical model for viscous incompressible flows. It reads

$$(NS_v) \quad \begin{cases} \partial_t \mathbf{u} + \mathbf{u} \cdot \nabla \mathbf{u} - \nu \Delta \mathbf{u} + \nabla p = 0, \\ \operatorname{div}(\mathbf{u}) = 0, \\ \mathbf{u} = 0 \quad \text{on} \quad \partial\Omega, \end{cases} \quad (1)$$

where $\mathbf{u}$ is the velocity, p is the pressure, and ν is the viscosity. We can define a typical length scale L and a typical velocity U . The dimensionless parameter or Reynolds number, $Re = UL/\nu$, is very important to compare the properties of different flows. Indeed, two flows having the same Re have the same properties. When Re is very large (ν very small), the Navier–Stokes system (NS_v) behaves like the Euler

system

$$(Euler) \quad \begin{cases} \partial_t \mathbf{U} + \mathbf{U} \cdot \nabla \mathbf{U} + \nabla p = 0, \\ \operatorname{div}(\mathbf{U}) = 0, \\ \mathbf{U} \cdot \mathbf{n} = 0 \quad \text{on} \quad \partial\Omega. \end{cases} \quad (2)$$

In the region close to the boundary, the length scale becomes very small and we cannot neglect viscous effects. In 1905, Ludwig Prandtl suggested that there exists a thin layer called the boundary layer, where the solution $\mathbf{u}$ undergoes a sharp transition from a solution to the Euler system to the no-slip boundary condition $\mathbf{u} = 0$ on $\partial\Omega$ of the Navier–Stokes system. In other words, $\mathbf{u} = \mathbf{U} + \mathbf{u}_{BL}$ where $\mathbf{u}_{BL}$ is small except near the boundary.

To illustrate this, we consider a two-dimensional (planar) flow $\mathbf{u} = (u, v)$ in the half-space $\{(x, y) \mid y > 0\}$ subject to the following initial condition $\mathbf{u}(t=0, x, y) = \mathbf{u}_0(x, y)$, boundary condition $\mathbf{u}(t, x, y=0) = 0$, and $\mathbf{u} \rightarrow (U_0, 0)$ when $y \rightarrow \infty$.

Taking the typical length and velocity of order one, the Reynolds number reduces to $Re = \nu^{-1}$. Let $\varepsilon = Re^{-1/2} = \sqrt{\nu}$.

Near the boundary, the Euler system is not a good approximation. We introduce new independent variables and new unknowns

$$\begin{aligned} \tilde{t} &= t, \quad \tilde{x} = x, \quad \tilde{y} = \frac{y}{\varepsilon}, \\ (\tilde{u}, \tilde{v})(\tilde{t}, \tilde{x}, \tilde{y}) &= \left(u, \frac{v}{\varepsilon}\right)(\tilde{t}, \tilde{x}, \varepsilon \tilde{y}). \end{aligned}$$

Notice that when $\tilde{y}$ is of order one, $y = \varepsilon \tilde{y}$ is of order ε . Rewriting the Navier–Stokes system in terms of the new variables and unknowns yields

$$\begin{cases} \tilde{u}_{\tilde{t}} + \tilde{u}\tilde{u}_{\tilde{x}} + \tilde{v}\tilde{u}_{\tilde{y}} - \tilde{u}_{\tilde{y}\tilde{y}} - \varepsilon^2 \tilde{u}_{\tilde{x}\tilde{x}} + p_{\tilde{x}} = 0, \\ \varepsilon^2 (\tilde{v}_{\tilde{t}} + \tilde{u}\tilde{v}_{\tilde{x}} + \tilde{v}\tilde{v}_{\tilde{y}} - \tilde{v}_{\tilde{y}\tilde{y}}) - \varepsilon^4 \tilde{v}_{\tilde{x}\tilde{x}} + p_{\tilde{y}} = 0, \\ \tilde{u}_{\tilde{x}} + \tilde{v}_{\tilde{y}} = 0. \end{cases} \quad (3)$$

Neglecting the terms of order ε^2 and ε^4 yields

$$\begin{cases} \tilde{u}_{\tilde{t}} + \tilde{u}\tilde{u}_{\tilde{x}} + \tilde{v}\tilde{u}_{\tilde{y}} - \tilde{u}_{\tilde{y}\tilde{y}} + p_{\tilde{x}} = 0, \\ p_{\tilde{y}} = 0, \quad \tilde{u}_{\tilde{x}} + \tilde{v}_{\tilde{y}} = 0. \end{cases} \quad (4)$$

Since p does not depend on $\tilde{y}$, we deduce that the pressure does not vary within the boundary layer and can be recovered from the Euler system (2) when $y = 0$, namely $p_x(t, x) = -(U_t + U U_x)(t, x, y=0)$, since $V(t, x, y=0) = 0$.

Going back to the old variables, we obtain

$$\begin{cases} u_t + uu_x + vu_y - \nu u_{yy} + p_x = 0, \\ u_x + v_y = 0 \end{cases} \quad (5)$$

which is the so-called Prandtl system. It should be supplemented with the following boundary conditions:

$$\begin{cases} u(t, x, y=0) = v(t, x, y=0) = 0, \\ (u, v)(t, x, y) \rightarrow (U(t, x, 0), 0) \quad \text{as} \quad y \rightarrow \infty. \end{cases} \quad (6)$$

Formally, a good approximation of $\mathbf{u}$ should be $\mathbf{U} + \mathbf{u}_{BL}$, where $\mathbf{U}$ is the solution of the Euler system (2) and $\mathbf{u}_{BL} + \mathbf{U}(t, x, 0)$ is the solution of the Prandtl system (5), (6).

Replacing the Navier–Stokes system by the Euler system in the interior and the Prandtl system near the boundary requires a justification. Mathematically, this can be formulated as a convergence theorem when ν goes to 0; namely, $\mathbf{u} - (\mathbf{U} + \mathbf{u}_{BL})$ goes to 0 when ν goes to 0 in L^∞ or in some energy space (see Masmoudi, 1998 for a special case). In its whole generality, this is still a major open problem in fluid mechanics. This is due to problems related to the well-posedness of the Prandtl system as well as problems related to the instability of some solutions to the Prandtl system, which may prevent the convergence.

Let us explain the first problem for the steady Prandtl system

$$\begin{cases} uu_x + vu_y - \nu u_{yy} + p_x = 0, \\ u_x + v_y = 0 \end{cases} \quad (7)$$

in $\Omega = \{(x, y) \mid 0 < x < X, y > 0\}$ subject to the following extra boundary condition $u(x=0, y) = u_0(y)$. Here, x should be thought of as a time-like variable. If we assume that $U, u_0 \geq 0$ and $u > 0$ if $y > 0$, we can introduce the von Mises transformation

$$(x, y) \rightarrow (x, \psi) \quad \text{and} \quad w = u^2,$$

where $\psi_y = u$, $\psi_x = -v$ and $\psi(x, 0) = 0$. In (x, ψ) , the steady Prandtl system reads

$$w_x = \nu \sqrt{w} w_{\psi\psi} - 2p_x,$$

which is a degenerate parabolic equation, with the boundary conditions

$$\begin{aligned} w(x, 0) &= 0, & w(0, \psi) &= w_1(\psi), \\ w(x, \psi) &\rightarrow U^2(x) & \text{as } \psi &\rightarrow \infty, \end{aligned}$$

where $w_1(\int_0^y u_1(s) ds) = u_1^2(y)$. Using this new equation, one can prove existence for the steady Prandtl system (see Oleinik and Samokhin, 1999). In the case of favorable pressure gradient, namely $p_x \leq 0$, the solution is global ($X = +\infty$). If $p_x > 0$, then a separation of the boundary layer may occur. x_0 is said to be a point of separation if $u_y(x_0, 0) = 0$ and $u_y(x, 0) > 0$ for $0 < x < x_0$. Qualitatively, the separation of the boundary layer is caused by a downward flow that drives the boundary layer away from the boundary. In that case, the assumption that the tangential velocity is large compared with the normal one is not valid, and the derivation of the Prandtl system is not justified.

A second obstacle to the convergence can come from the instability of the solution to the Prandtl system itself, if we consider a two-dimensional shear flow $\mathbf{u}^s = (u^s(y), 0)$, which is a steady solution of the Euler system. It is well known that the linear stability of such

a flow is linked to the presence of inflection points in the profile u^s . A necessary condition of instability is that the profile has an inflection point. The solution to the Prandtl system with initial data $\mathbf{u}^s$ and $\mathbf{U} = 0$ is just the solution of a heat equation $u_t = \nu u_{yy}$. If the profile $\mathbf{u}^s$ is linearly unstable for the Euler system, then $\mathbf{u}$ is not a good approximation of the Navier–Stokes system when ν goes to 0 (see Grenier, 2000).

The boundary layer theory is a very powerful tool in asymptotic analysis and is present in many different fields of partial differential equations, including the magnetohydrodynamic flow boundary layer. In fluid mechanics and atmospheric dynamics, we can also mention the Ekman layer, which is due to the balance between the viscosity and the rapid rotation of a fluid (Coriolis forces). In kinetic theory, systems of conservation laws, passage to the limit from a parabolic to a hyperbolic system, different types of boundary layers arise.

BOUNDARY VALUE PROBLEMS

For a given ordinary or partial differential equation, a boundary value problem (BVP) requires finding a solution of the equation valid in a bounded domain and satisfying a set of given conditions on the boundary of a domain. To define a boundary value problem, therefore, one needs to give an equation, a domain, and an appropriate number of functions supported on the boundary of the given domain, defining the boundary conditions. For example,

$$\begin{aligned} q_t + q_x + q_{xxx} &= 0, & \text{the PDE,} \\ x &\in [0, \infty), & t \in [0, T], & \text{the domain,} \\ q(x, 0) &= f_0(x), & q(0, t) &= g_0(t), & \text{the boundary} \\ & & & & \text{conditions.} \end{aligned}$$

Finding a solution of a given BVP is more difficult than finding a function that satisfies the PDE, because of

the constraint imposed on the solution at the boundary of the domain. Indeed, for nonlinear equations, there exists no general method to find the solution of a given BVP. The question of the solvability of such a problem must also be addressed, and in general, it does not have an easy answer (in the above example, if we prescribe two rather than just one condition at the boundary $x = 0$, there exists, in general, no solution). The existence and uniqueness of the solution of a given BVP can be guaranteed only when a specific, well-defined number of boundary conditions are prescribed, and this number depends on the highest-order derivatives appearing in the equation with respect to each variable (Coddington & Levinson, 1955).

For linear ordinary differential equations (ODEs), there is a general methodology for solving a BVP, based on defining the particular solution of a related problem. This particular solution is called the Green function associated with the BVP, and it depends on the boundary conditions. The Green function is used to define an integral operator, and if this operator is sufficiently regular, one can use it to express the solution of the original problem (Stackgold, 1979). This approach is powerful and fairly general, but it is not always successful, and it cannot be used for nonlinear equations.

No general methods are available to construct solutions for nonlinear ODEs or even to assert their existence. Most techniques rely on perturbing in some way the solution of an associated linearized problem or an integrable nonlinear problem. If one hopes to extract information about the nonlinear problem by studying a corresponding linearized one, the correct way to linearize must also be evaluated. Examples of such techniques are branching theory, eigenvalue perturbation, and boundary conditions or domain perturbation.

For linear PDEs in two variables, the classical approach for solving a BVP (going back to Jean D'Alembert's work in the 1740s) is separation of variables. The aim of this technique is to reduce the problem to two distinct linear problems for two ODEs. However, the separability of the problem depends on the specific domain and boundary conditions. For example, depending on the specific boundary conditions prescribed, the ODE one obtains may lead, via the associated Green function, to a non-self-adjoint transform problem, for which few general results are available.

An important theoretical result for the solvability of BVP for linear PDEs is the fundamental principle of Ehrenpreis (1970), which states that there always exists an appropriate generalization of the Fourier transform capable of representing the general solution of a BVP for a linear PDE in the variables (x_1, x_2) , posed in a smooth convex domain. This result assumes the well-posedness of the problem. It then ensures that there

exists a measure $\rho(k)$ and a contour Γ in the complex plane such that the solution of the problem can be expressed as an integral in the form

$$\int_{\Gamma} e^{f_1(k)x_1 + f_2(k)x_2} d\rho(k),$$

where k is a complex parameter. The functions $f_1(k)$ and $f_2(k)$ are given explicitly. For example, in the case of an evolution equation $u_t = Lu$, where $u = u(x, t)$ and L is a linear differential operator, the representation takes the form

$$u(x, t) = \int_{\Gamma} e^{ikx - i\omega(k)t} d\rho(k), \quad (1)$$

where $\omega(k)$ is the dispersion relation of the equation. In representation (1), the dependence on the solution variables (x, t) is explicit; the integration variable k is called the spectral parameter, and such a representation is said to be spectrally decomposed. However, this result is, in general, not constructive, as $\rho(k)$ and Γ are not known. In some cases, it is possible, to obtain this representation via separation of variables, but this is not always the case. Consider, for example, the second-order BVP

$$\begin{aligned} i q_t + q_{xx} &= 0, \quad 0 < x < \infty, \quad 0 < t < \infty, \\ q(x, 0) &= q_0(x), \quad q(0, t) = f(t), \end{aligned} \quad (2)$$

where $q = q(x, t)$ and it is assumed that all functions are infinitely differentiable and vanish as $x \rightarrow \infty$. By separating variables, one obtains an ODE in x , which can be solved using the sine transform. Assuming that a unique solution exists, this procedure yields the representation

$$\begin{aligned} q(x, t) &= \frac{2}{\pi} \int_0^{\infty} \sin(kx) e^{-ik^2 t} \\ &\quad \times \left(\hat{q}_0(k) + ik \int_0^t e^{ik^2 s} f(s) ds \right) dk, \end{aligned}$$

where

$$\hat{q}_0(k) = \int_0^{\infty} \sin(kx) q_0(x) dx.$$

This representation is not in form (1) as the variable t also appears as a limit of integration. This fact not only makes this representation less convenient for extracting information about the t dependence of the solution but also makes the rigorous proof of existence and uniqueness of a solution more cumbersome, as the relevant integral is not uniformly convergent as $x \rightarrow 0$.

For nonlinear PDEs, no general method is available (Logan, 1994). Perturbation techniques can be of some use in the study of evolutionary PDEs of the form $u_t + P(u) = 0$, where $u = u(t, x)$ and Pu is a nonlinear ODE containing the x -derivatives. Solutions of this problem such that $u_t = 0$ are called steady-state

solutions: these are the solutions that are independent of time. In this context, one studies the linearized stability of the steady state by using the same perturbative techniques discussed for ODEs, as this yields information about the qualitative behavior in time of the solution of the nonlinear problem. The results available in this area are, in general, of limited applicability and practical use for finding explicit solutions.

The special class of nonlinear PDEs known as integrable deserves separate consideration. For these equations, there exists a particular linearizing technique, the inverse scattering transform, which yields the solution of the Cauchy problem. Some of these equations, such as the Korteweg–de Vries and sine-Gordon equations, have been considered on simple domains, and specific BVPs have been solved by ad hoc PDE techniques. The first such result was obtained already 40 years ago (Cattabriga, 1959), but recently this field has witnessed a new surge of interest. To obtain such results, the nonlinear problem is often considered as a linear problem, with the nonlinear term considered as a nonhomogeneous (or forcing) term; thus, the analysis is based on the analysis of the linearized equations by classical PDE techniques (Bona et al., 2001). A different approach involves the attempt to extend the inverse scattering linearizing technique to BVPs, as done, for example, in Leon (2002) for the sine-Gordon equation.

Recently, a general approach to solving BVPs for two-dimensional linear PDEs has been proposed and successfully used to solve many different types of such problems (Fokas, 2000). Its relevance is enhanced by the fact that this approach can be generalized to treat integrable nonlinear PDEs. This methodology yields a spectral transform associated directly to the PDE rather than to transforms associated to the two ODEs obtained by separating variables. For Example (2), this yields, for the solution, the representation

$$q(x, t) = \frac{1}{2\pi} \int_0^\infty e^{ikx - ik^2 t} \hat{q}_0(k) dk + \frac{1}{2\pi} \int_\Gamma e^{ikx - ik^2 t} \hat{q}(k) dk,$$

where Γ is the boundary of the first quadrant of the complex k -plane, and

$$\hat{q}(k) = \frac{\hat{q}_0(k) + \hat{q}_0(-k)}{2} - k \int_0^\infty e^{ik^2 t} f(t) dt.$$

This representation is in Ehrenpreis form, and in addition, measure and contour are explicitly constructed.

The above-mentioned approach provides a unification of the integral representation of the solution of a linear PDE in terms of the Ehrenpreis fundamental principle with the inverse scattering transform for inte-

grable nonlinear PDEs. Indeed, when the problem reduces to an initial value problem for decaying solutions (i.e., the domain for the spatial variable is the whole real line, and the solution is assumed to vanish at $\pm\infty$), the transform obtained is precisely the inverse scattering transform.

The essential ingredients of this approach are the reformulation of the PDE as the closure condition of a certain differential form, and the definition in the complex plane of a Riemann–Hilbert problem depending on both the PDE and the domain. The differential form can be found algorithmically for linear PDEs and is equivalent to the Lax pair formulation for integrable nonlinear PDEs (Lax, 1968). The solution of this Riemann–Hilbert problem (which can be found in closed form in many cases) takes the role of the classical Green formula, and yields an integral representation for the solution, which is independent of the particular boundary conditions and indeed contains all the boundary values of the solution. What this approach crucially provides (when the definition domain is connected) is a global relation among these boundary values, which is the tool necessary to express the solution only in terms of the given boundary conditions and to prove rigorously problems with well-posedness, as well as existence and uniqueness results.

BRANCHING LAWS

In this entry, we briefly trace the history of a familiar phenomenon, branching, in physical and biological systems and the laws governing them. The simplest type of branching tree is one in which a single conduit enters a vertex and two conduits emerge. This dichotomous process is clearly seen in the patterns of biological systems, such as botanical trees, neuronal dendrites, lungs, and arteries, as well as in the patterns of physical systems, such as lightning, river networks, and fluvial landscapes. The quantification of branching through the construction of the mathematical laws that govern them can be traced back to Leonardo da Vinci (1452–1519). In his *Notebooks*, he writes (Richter, 1970):

All the branches of a tree at every stage of its height when put together are equal in thickness to the trunk [below them]. All the branches of a water [course] at every stage of its course, if they are of equal rapidity, are equal to the body of the main stream.

He also admonished his readers with: “Let no man who is not a Mathematician read the elements of my work.” This statement increases in significance when we consider that da Vinci wrote nearly two centuries before Galileo (Galilei, 1638), who is generally given the credit for establishing the importance of mathematics in modern science.

The first sentence in the da Vinci quote is further clarified in subsequent paragraphs of the *Notebooks*. With the aid of da Vinci’s sketch reproduced in Figure 1, this sentence has been interpreted as follows: if a tree has a trunk of diameter d_0 that bifurcates into two limbs of diameters d_1 and d_2 , the three diameters are related by

$$d_0^2 = d_1^2 + d_2^2 \quad (1)$$

Simple geometrical scaling yields the diameter exponent $\alpha = 2$, which corresponds to rigid pipes carrying fluid from one level of the tree to the next, while retaining a fixed cross-sectional area through successive generations of bifurcation. Although the pipe model has a number of proponents from hydrology, the diameter exponent for botanical trees was determined empirically by Cecil D. Murray in 1927 to be insensitive to the kind of botanical tree and to have a value 2.59 rather than 2 (Murray, 1927). Equation (1) is referred to as Murray’s law in the physiology literature.

Figure 1. Sketch of tree from Leonardo da Vinci’s *Notebooks*, PL XXVII (Richter, 1970).

The significance of Murray’s law was not lost on D’Arcy Thompson (1942). In the second edition of his classic *On Growth and Form*, first published in 1917, Thompson argues that the geometrical properties of biological systems can often be the limiting factor in the development and final function of an organism. This is stated in his principle of similitude, which is a generalization of certain observations made by Galileo regarding the trade-off between the weight and strength of bone (Galilei, 1638). Thompson goes on to argue that the design principle for biological systems is that of energy minimization.

The second sentence in the da Vinci quotation is as suggestive as the first. In modern language, we would interpret it to mean that the flow of a river remains constant as tributaries emerge along the river’s course. This equality must be true in order for the water to continue flowing in one direction and not stop and reverse course at the mouth of a tributary. Using the pipe model introduced above, and minimizing the energy with respect to the pipe radius, yields $\alpha = 3$, in Equation (1). Thus, the value of the diameter exponent obtained empirically by Murray falls between the theoretical limits of geometric self-similarity and hydrodynamic conservation, $2 \leq \alpha \leq 3$.

In da Vinci’s tree, it is easy to assign a generation number to each of the limbs, but the counting procedure can become complicated in more complex systems like the generations of the bronchial tubes in the mammalian lung. One form taken by the branching laws is that the ratio of the radii of the tubes (from one generation to the next) is constant, that is, by the scaling relation

$$\frac{r_j}{r_{j+1}} = R. \quad (2)$$

Equation (2) is analogous to Horton’s law for river trees and fluvial landscapes, which involves the ratio

of the number of branches in successive generations of branches, rather than radii (Mandelbrot, 1977). In either case, the parameter R determines the branching law and Equation (2) implies a geometrical self-similarity in the tree, as anticipated by Thompson. In the branching of bronchial airways, $d_1 = d_2$ at each stage of the tree, so that from Equation (1) we deduce the relationship between the radii of the pipes between successive generations as

$$r_j = 2^{1/\alpha} r_{j+1}. \quad (3)$$

In the case of the lung, the diameter of an airway is reduced by a factor $2^{-1/3}$ at each generation, since $\alpha = 3$ for the bronchial tree. Therefore, after j generations, $r_j = r_0 \exp(-j/\lambda)$, where the exponential rate of reduction, $\lambda = \ln(2)/3$, is the same for each generation beyond the trachea r_0 , as argued by Weibel (2000).

A less space-filling value of the scaling index is obtained for the arterial system, where it is empirically determined that $\alpha = 2.7$. For a general non-integer branching index, the scaling relation Equation (3) defines a fractal tree. Such trees have no characteristic scale length and were first organized and discussed as a class by Benoit Mandelbrot (1977)—the father of fractals. The classical approach relied on the assumption that biological processes, like their physical counterparts, are continuous, homogeneous, and regular. However, most biological systems and many physical ones are discontinuous, inhomogeneous, and irregular and are necessarily that way in order to perform a particular function, such as gas exchange in lungs and arteries.

An entirely different kind of fractal tree is that of neuronal dendrites. The branching trees of neurons interleave the brain and form the communication system within the body. In the neurophysiology literature, Equation (1) is known as Rall's law with $\alpha = 1.5$ (Rall, 1959). More recent measurements of the scaling index, at each generation of dendritic branching, show a change with generation number; that is, the single parameter R is replaced with R_j . This non-constant scaling coefficient implies that Thompson's principle of similitude is violated.

A fractal model of the bronchial tree assumes that the ratio of successive generations of radii is dependent on the generation number, giving rise to a renormalization group relation, with the solution given by

$$r_j = \frac{a(j)}{j^\mu}, \quad j > 0. \quad (4)$$

Here, the average radius is an inverse power law in the generation number j , modulated by a slowly oscillating function $a(j)$ as observed in the human, dog, rat, and hamster data shown in Figure 2 (West & Deering, 1994). In this way, the fractal concept is used as a design principle in biology (Weibel, 2000; West, 1999;

Figure 2. The variation in diameter d of the bronchial airways is depicted as a function of generation number j for rats, hamsters, humans, and dogs. The modulated inverse power law from the fractal model of the bronchial airway is observed in each case (West & Deering, 1994).

Mandelbrot, 1977) and in the development of branching laws.

BREATHERS

The term *breather* (also called a “bion”) arose from studies of the sine-Gordon (SG) equation

$$u_{tt} - u_{xx} + \sin u = 0, \quad (1)$$

which has localized solutions that oscillate periodically with time and decay exponentially in space. Such a

solution of Equation (1) is given by

$$u(x, t) = 4 \tan^{-1} \left[\frac{\lambda \sin \omega t}{\omega \cosh \lambda x} \right], \quad \lambda = \sqrt{1 - \omega^2}, \quad (2)$$

which is shown in Figure 1.

Although the breather of Equation (2) is a non-topological soliton of Equation (1), it can be considered as a bound state of two topological solitons of the SG equation (kink and antikink), one of which is shown in Figure 2(a). The kink and antikink oscillate with respect to each other with the period $T = 2\pi/\omega$. Thus, such a soliton is also called a “doublet.” A sketch of the bion at small frequencies ($\omega \ll 1$) and large enough t is presented in Figure 2(b). At some initial time, the kink and antikink move outward in opposite directions and separate in space with increasing time up to some finite distance (at $t = T/4$). The kink and antikink components of the breather never become fully free of distortions in their shapes due to interactions between each other, and finally oscillate in a kind of bound state.

At $1 - \omega^2 \ll 1$, Equation (2) reduces to a small-amplitude breather $u(x, t) = 4 \operatorname{Re} \psi(x, t)$, where

$$\psi(x, t) = -i \frac{\lambda \exp(-i\omega t)}{\cosh \lambda x} \quad (3)$$

and $\lambda = \sqrt{2(1 - \omega)}$. Equation (3) is a soliton solution of the nonlinear Schrödinger (NLS) equation

$$i\psi_t + \frac{1}{2} \psi_{xx} - \psi + |\psi|^2 \psi = 0, \quad (4)$$

which is regarded as a breather and can be written as $\psi(x, t) = \phi(x) \exp(i\omega t)$. In this form, the spatial dependence of the soliton amplitude and the time dependence of the phase (of the complex function ψ) are separated. As a result, the nonlinearity appears only in the amplitude, but not in the phase of the NLS soliton. Although such a separation of the spatial and time dependencies in a soliton expression does not take place in the general form of the SG breather, the limiting case of the SG breather coincides with the amplitude of the NLS soliton.

At present, it is not known whether other nonlinear Klein–Gordon equations similar to Equation (1), but differing from it only by the nonlinear term, possess exact breather solutions (Segur & Kruskal, 1987). However, if certain nonlinear terms in a Klein–Gordon-type equation differ only slightly from $\sin u$ (slightly perturbed SG equation), a breather-like solution may persist in the first order with respect to the perturbation (Birmir et al., 1994).

The breather of the SG equation can move along the space coordinate axis with a stationary velocity V . As Equation (1) is a relativistic invariant equation (invariant under a Lorentz transformation

Figure 1. $u(x, t)$ from Equation (2) versus x for 26 different times equally spaced and covering one period, with $\lambda = 0.5$.

Figure 2. (a) A sketch of the sine-Gordon kink. (b) Three profiles of the kink-antikink oscillations.

of the independent variables), one can obtain a moving breather from Equation (2) substituting $x \rightarrow (x - Vt)/(1 - V^2)^{1/2}$ and $t \rightarrow (t - Vx)/(1 - V^2)^{1/2}$. Consequently, the moving breathers form a two-parametric (ω and V) family of solutions of the SG equation.

Possible values of the breather parameters ω and V can be compared with the dispersion relation ($\omega^2 = 1 + k^2$) for small vibrations (phonons) described by the linearized version of Equation (1). These phonons have frequencies $\omega > 1$ and phase velocities $\omega/k > 1$. A breather frequency, on the other hand, is smaller than the minimum frequency of the phonons ($\omega < 1$), and the breather velocity is smaller than the minimum phonon phase velocity ($V < 1$). Therefore, the dynamical breather parameters lie outside of the spectrum of the linear vibrations. Although the time dependence of the breather includes the higher temporal harmonics of the oscillations, the phonons cannot be resonantly excited by the breather. Thus, breathers and phonons are asymptotically independent vibrational

modes of the system described by the SG equation. This asymptotic independence of nonlinear excitations (breathers and kinks) and phonons follows from the integrability of Equation (1).

An important way to study nonlinear integrable equations is the inverse scattering method. According to this method, breathers are characterized by poles in the complex phase plane of scattering parameters for the equation under consideration.

It is known that several nonlinear differential equations possess breather solutions. The Landau–Lifshitz (LL) equation provides an example of a nonlinear equation generalizing the results that are described by the SG and NLS equations. The breather-like solution of the LL equation has a more complicated form than the one presented above; however, it is also a two-parameter soliton called a dynamic magnetic soliton (Kosevich et al., 1977). Its oscillatory behavior is characterized by a frequency ω , and its center can move with a velocity V . In the general case, the magnetic soliton can be described by some complex function of x and t , but the time and spatial dependencies are not separated in the analytical expression for such a soliton.

An important class of breathers the so-called discrete breathers (also known as intrinsic localized modes, self-localized anharmonic modes, or nonlinear localized excitations). These are solutions of a nonlinear equation on a lattice, and they are periodic in time and localized in space. Although most such investigations are performed by numerical calculations, there exist nonlinear dynamic equations on a lattice possessing exact analytical breather solutions. One of them is the following discrete version of the NLS equation proposed by Ablowitz and Ladik (AL) in 1976 (Ablowitz & Ladik, 1976):

$$i\partial_t \psi_n - (\psi_{n+1} + \psi_{n-1})(1 + |\psi_n|^2) = 0. \quad (5)$$

The AL lattice is integrable and it allows for breather-like solutions, the simplest of which has a form close to that of Equation (2):

$$\psi = \frac{\sinh \beta \exp(-i\omega t)}{\cosh \beta(n - x_0)}, \quad (6)$$

where n is the integer number of a lattice site, $x_0 = \text{constant}$, and $\omega = -2 \cosh \beta$.

BROUWER'S FIXED POINT THEOREM

See Winding numbers

BROWNIAN MOTION

In 1828, Robert Brown, a leading botanist, observed that a wide variety of particles suspended in liquid exhibit an intrinsic, irregular motion when viewed under a microscope. While not the first to witness such motion, his experimental focus on this phenomenon, which would bear his name, established its universality and intrinsic nature, thereby raising it as an issue for fundamental scientific inquiry (Nelson, 1967). Deutsch has recently raised the question of whether Brown actually witnessed Brownian motion or fluctuations due to some external contaminating influence (Peterson, 1991). Indeed, while Brownian motion is a ubiquitous phenomenon, not all irregular motions can be ascribed to Brownian motion. The dancing of dust particles in sunlight is dominated by imperceptible turbulent currents, not Brownian motion. True Brownian motion is generally only visible on scales of microns and below, but has important macroscopic ramifications because all microscopic particles manifest it. For example, Brownian motion makes possible both the fine-scale mixing of initially segregated substances in nature and industry, as well as the passive transport of ions, nutrients, and fuel, which allow biological cells to support life.

The origin of Brownian motion remained under debate throughout the 19th century, with Cantoni, Delsaux, Gouy, and C. Weiner proposing that thermal motions in the suspending liquid were responsible, as discussed in Einstein (1956, pp. 86–88), Gallavotti (1999, Chapter 8), and Russel et al. (1989, pp. 65–66). Attempts to examine this hypothesis quantitatively were hampered by the inability to measure accurately the velocity of particles undergoing Brownian motion, since such motion loses coherence over time scales (microseconds) that are shorter than those which experimental observations were able to resolve. In

one of three ground-breaking papers that Einstein published in 1905, he offered a statistical mechanical means for theoretical calculations involving Brownian motion (Einstein, 1956). Einstein realized that the quantity involving Brownian motion that can be best observed under a microscope in an experiment is the “diffusivity”:

$$D = \lim_{t \rightarrow \infty} \frac{|X(t) - X(0)|^2}{2t}, \quad (1)$$

where $X(t)$ denotes the observed displacement of the Brownian particle along a fixed direction at time t . In practice, t is simply taken as some satisfactorily long time of observation, and there is no need for fine temporal resolution as there would be if the velocity were to be measured. Einstein employed a random walk model for his analysis and showed that the diffusivity defined in (1) is identical to the diffusion constant that describes the macroscopic evolution of the concentration density $n(\mathbf{x}, t)$ of a large number of Brownian particles:

$$\frac{\partial n(\mathbf{x}, t)}{\partial t} = D \sum_{j=1}^3 \frac{\partial^2 n(\mathbf{x}, t)}{\partial x_j^2}. \quad (2)$$

Through an elegant argument based on *equilibrium* statistical mechanical arguments, Einstein showed that the diffusivity D of a Brownian particle must be related to its friction coefficient ξ in the following way:

$$D = \frac{k_B T}{m\xi}, \quad (3)$$

where k_B is Boltzmann’s constant and T is the absolute temperature (measured in Kelvin scale), and m is the particle’s mass. The friction coefficient ξ appears in the relation between the drag force F_{drag} and velocity v of the particle in steady-state motion (assuming a low Reynolds number):

$$F_{\text{drag}} = m\xi v. \quad (4)$$

For a sphere of radius a moving through a fluid with dynamic viscosity μ , the friction coefficient is given by $\xi = 6\pi\mu a/m$. The remarkable property of the “Einstein relation” in (3) is that it links a quantity D pertaining to statistically unpredictable dynamical fluctuations to a quantity ξ , which involves deterministic, steady-state properties. Later work generalized the Einstein relation (3) to “fluctuation-dissipation theorems,” which express the structure of the spontaneous statistical fluctuations in a wide class of physical systems to the structure of the dissipative (frictional) dynamics (Kubo et al., 1991, Chapter 1).

The basic theory of Brownian motion was developed by Einstein in 1905, a time when the premises of the atomic theory of matter were still not yet fully agreed upon (Gallavotti, 1999; Nelson, 1967). Einstein realized that a careful observation of Brownian motion and his relation between the diffusivity of

a Brownian particle and its mobility could be used to calculate the number of particles making up a given mass of fluid if the atomic theory were valid. Under a microscope sufficient to resolve the Brownian motion of a particle, all quantities in (3) are directly observable except for Boltzmann’s constant k_B . Therefore, the Einstein relation (3) can be used to compute a value for k_B based on Brownian motion data. Now, k_B is in turn related to Avogadro’s number N_A , which is the number of molecules in a “mole” (a certain well-defined macroscopic amount) of a substance. The Brownian motion data and the Einstein relation, therefore, furnish an independent prediction for Avogadro’s number N_A and, thereby, the number of molecules per unit mass of the fluid. In other words, the number (and therefore mass) of the individual fluid particles could be calculated without having to observe them at an individual level, an experimental feat that has become possible only in recent years. Instead, their individual mass and number could be assessed through their collective influence on a much larger and, therefore, observable immersed particle. In 1908, Jean Perrin experimentally confirmed that the value of N_A computed in this way agreed with those obtained from other techniques (Gallavotti, 1999), providing strong support for the atomic theory of matter. Since the 1970s, Brownian motion has been investigated in the laboratory through dynamic light scattering techniques (Russel et al., 1989, Chapter 3).

The most idealized mathematical representation of Brownian motion with diffusivity D is defined as $(2D)^{1/2}W(t)$, where $W(t)$ is a canonical continuous random process with Gaussian statistics such that $W(0) = 0$, $\langle W(t) \rangle = 0$, and

$$\langle (W(t) - W(t'))^2 \rangle = |t - t'|. \quad (5)$$

This mathematical Brownian motion is often referred to as the Wiener process (Borodin & Salminen, 2002; Gallavotti, 1999; Nelson, 1967). This idealized Brownian motion has independent increments (no inertia). Physical Brownian motion, of course, has some small inertia as well as several other complicating influences from the fluid environment and from the presence of other nearby Brownian particles (Russel et al., 1989). These extra features can be built into a dynamical description using the mathematical Brownian motion as the basic noise input with influence mediated by the other physical parameters. The mathematical Brownian motion has a similar role in modeling noise input in a wide variety of stochastic models in physics, biology, finance, and other fields. More precisely, the Levy–Khinchine theorem indicates that in any system affected by noise in a continuous way such that the noise on disjoint time intervals is independent can be modeled in terms of mathematical Brownian motion (Reichl, 1998, Chapters 4, 5).

Figure 1. Sample trajectories of fractional Brownian motion using Fourier-wavelet method (Elliott et al., 1997). Top panel: $H = \frac{1}{3}$, lower panel: $H = \frac{2}{3}$. Both simulations used the same random numbers.

Discontinuous noise-induced jumps, in contrast, are modeled in terms of Poisson processes or more generally Lévy processes (Reichl, 1998, Chapters 4, 5). Continuous noise with long-range correlations (so that the independent increment property is not satisfied), on the other hand, can often be usefully modeled in terms of “fractional Brownian motion” (FBM) (Mandelbrot, 2002). This is an idealized Gaussian random process $Z(t)$ with $Z(0) = 0$, $\langle Z(t) \rangle = 0$, and

$$\langle (Z(t) - Z(t'))^2 \rangle = |t - t'|^{2H} \quad (6)$$

where the Hurst exponent H is chosen from the interval $0 < H < 1$. The FBM with $H = \frac{1}{2}$ corresponds to ordinary Brownian motion with independent increments. FBMs with $\frac{1}{2} < H < 1$ have positive, long-ranged correlations with less rough trajectories and large excursions, while FBMs with $0 < H < \frac{1}{2}$ have negative, long-ranged correlations with rougher trajectories and a more oscillatory character (Figure 1). All FBMs have a statistical self-similarity property; the statistics of the rescaled FBM $\lambda^{-H} Z(\lambda t)$ are identical to those of the original $Z(t)$. That is, these processes have no finite length or time scale associated to them and can be thought of as random fractals. Fractional Brownian motions are therefore particularly appropriate for modeling systems with fluctuations occurring over a wide range of scales; cutoff lengths

can be introduced by filtering an input FBM. Models built from FBMs have been developed in turbulence theory, natural landscape and cloud structures, surface adsorption processes, neural signals in biology, and self-organized critical systems such as earthquakes, forest fires, and sandpiles.

BRUSSELATOR

The Brusselator is an autocatalytic model involving two intermediates. It illustrates how the fundamental laws of thermodynamics and chemical kinetics as applied to open systems far from equilibrium can give rise to self-organizing behavior and to dissipative structures in the form of temporal oscillations and spatial pattern formation.

Chemical kinetics imposes stringent conditions on the concentrations of the species involved in a reaction scheme and on the associated parameters. In a scheme consisting entirely of elementary steps, the overall rates are given (in an ideal system) by mass action kinetics, featuring particular combinations of products of concentrations preceded by stoichiometric coefficients (integer numbers specifying how the relevant constituents are produced or consumed). This guarantees the positivity of the solutions of the mass balance equations. A second condition is detailed balance, which requires that in chemical equilibrium, each individual reaction step is balanced by its inverse (See **Detailed balance**). This gives rise to relations linking the concentrations of initial reactants and final products to the rate constants, independent of the concentrations of the intermediates.

An additional set of requirements stems from the fact that self-organization in chemical kinetics must arise through an instability. One reason for this is that equilibrium and the states in its vicinity, obtained as the constraints are gradually increased (called the "thermodynamic branch"), are stable. To overcome this property and evolve to states that are qualitatively different from equilibrium, new branches of solutions must be generated, which can only take place through the mechanisms of instability and bifurcation. This, in turn, requires that the non-equilibrium constraints exceed a critical value (Glandsdorff & Prigogine, 1971). Because the evolution laws generated by chemical kinetics at the macroscopic level of description are dissipative, the bifurcating states are attractors, attained by families of initial conditions belonging to an appropriate part of phase space. This guarantees structural stability, that is to say, the robustness of the solution toward small perturbations—a condition to be fulfilled by a model aiming to describe a physical phenomenon. Note that non-equilibrium instabilities and self-organization collapse when the

system becomes closed to the external environment or when the kinetics involves only first-order steps, in which case one obtains a monotonic decay to a unique steady state (Denbigh et al., 1948).

Following the pioneering work of Alfred Lotka, several authors in the late 1940s, proposed models of open nonlinear systems deriving from mass action kinetics and giving rise to sustained oscillations (Lotka, 1956; Moore, 1949). These models do not have structural stability (as they give rise to a continuum of initial condition-dependent solutions), and they do not exhibit the role of the constraints in a transparent manner (as they are usually formulated in the limit of irreversible reactions). When the non-equilibrium constraints are explicitly accounted for, it is found (Lefever et al., 1967) that there is no instability threshold in these models. As the first known chemical model that is both fully compatible with the laws of thermodynamics and chemical kinetics and generates dissipative structures through non-equilibrium instabilities, the Brusselator is free from such deficiencies.

Model Presentation

In the interest of transparency, one desires a minimal model, and if oscillatory behavior is one of the required properties, this necessitates two coupled variables representing the concentrations of intermediate products. As in the models of the Lotka family, one seeks steps that are not only nonlinear but also include feedback processes, the simplest chemical version of which is autocatalysis. But contrary to these models, one now needs to scan the whole range of near to far from equilibrium situations and to undergo an instability somewhere in this range. As the Lotka-type models contain only second-order steps, a natural solution is to amend them by replacing these steps by a third-order one. This leads to the scheme (Prigogine & Lefever, 1968)

Hanusse, Tyson, and Light have shown that a two-variable system compatible with the above requirements necessarily comprises a third-order step. Here A , B are the initial reactants, D , E the final products, and X , Y the intermediates: X can be thought of as an activator generating Y at its own expense, which acts as an inhibitor if the B concentration is large.

From the standpoint of irreversible thermodynamics, the Brusselator can be driven out of equilibrium through two independent constraints (affinities) related to the

overall reactions

This offers sufficient flexibility to allow one to take the limit of purely irreversible steps and of fixed reactant and product concentrations (also referred to as pool chemical approximation, ensuring that the (X, Y) subsystem becomes open to the external environment), while satisfying the positivity of concentrations, detailed balance, and mass conservation (Lefever et al., 1988). When diffusion is also included, and upon performing a suitable scaling transformation, this leads to the Brusselator equations

$$\begin{aligned} \frac{\partial X}{\partial t} &= A - (B + 1)X + X^2Y + D_x \nabla^2 X, \\ \frac{\partial Y}{\partial t} &= BX - X^2Y + D_y \nabla^2 Y \end{aligned} \quad (2)$$

in which B , D_x/D_y , and the system size usually play the role of the parameters controlling the instabilities.

A number of variants of this canonical form have also been developed, including Brusselator in an open well-stirred reactor, Brusselator in a non-ideal system, including coupling between non-equilibrium instabilities and phase transitions, and coupling with external fields or advection.

Behavior of the Solutions

Since the first bifurcation analysis of the Brusselator equations (Nicolis & Auchmuty, 1974), several studies have been devoted to the various modes of spatiotemporal organization generated by Equations (2): limit cycles, Turing patterns, and traveling waves in one-dimensional systems (Nicolis & Prigogine, 1977); spatiotemporal chaos arising from the diffusive coupling of local limit cycle oscillators (Kuramoto, 1984); patterns in two- and three-dimensional systems including patterns arising from the interference of different instability mechanisms such as Turing, Hopf (De Wit, 1999); and the effect of confinement (Herschkowitz-Kaufman & Nicolis, 1972). Many phenomena now known to be generic have first been discovered on these Brusselator-based analyses, which have also helped to test the limits of traditional theoretical approaches and to explore new methodologies such as normal forms and phase dynamics.

The Brusselator has also been used to explore possible thermodynamic signatures of dissipative structures. No clearcut tendencies seem to exist, suggesting that global thermodynamic quantities like entropy and entropy production do not provide adequate measures of dynamic complexity. Finally, attention has been focused on the new insights afforded when the mean-field equations (2) are augmented to account for fluctuations, a study for which the

Brusselator is well suited thanks to its mechanistic basis. The interest here is to provide a fundamental understanding of how large-scale order can be sustained despite the locally prevailing thermal disorder. Early accounts of the results, with emphasis on critical behavior in the vicinity of bifurcations, can be found in Nicolis & Prigogine (1977) and in Walgraef et al. (1982).

BURGERS EQUATION

In 1915, Harry Bateman considered a nonlinear equation whose steady solutions were thought to describe certain viscous flows (Bateman, 1915). This equation, modeling a diffusive nonlinear wave, is now

widely known as the Burgers equation, and is given by

$$u_t + uu_x = \frac{\mu}{2} u_{xx}, \quad (1)$$

where μ is a constant measuring the viscosity of the fluid. It is a nonlinear parabolic equation, simply describing a temporal evolution where nonlinear convection and linear diffusion are combined, and it can be derived as a weakly nonlinear approximation to the equations of gas dynamics.

Although nonlinear, Equation (1) is very simple, and interest in it was revived in the 1940s, when Dutch physicist Jan Burgers proposed it to describe a mathematical model of turbulence in gas (Burgers, 1940). As a model for gas dynamics, it was then studied extensively by Burgers (1948), Eberhard Hopf (1950), Julian Cole (1951), and others, in particular; after the discovery of a coordinate transformation that maps it to the heat equation. While as a model for gas turbulence the equation was soon rivaled by more complicated models, the linearizing transformation just mentioned added importance to the equation as a mathematical model, which has since been extensively studied. The limit $\mu \rightarrow 0$ is a hyperbolic equation, called the inviscid Burgers equation:

$$u_t + uu_x = 0. \quad (2)$$

This limiting equation is important because it provides a simple example of a conservation law, capturing the crucial phenomenon of shock formation. Indeed, it was originally introduced as a model to describe the formation of shock waves in gas dynamics.

A first-order partial differential equation for $u(x, t)$ is called a conservation law if it can be written in the form

$$u_t + (f(u))_x = 0.$$

For Equation (2), $f(u) = u^2/2$. Such conservation laws may exhibit the formation of shocks, which are discontinuities appearing in the solution after a finite time and then propagating in a regular manner. When this phenomenon arises, an initially smooth wave becomes steeper and steeper as time progresses, until it forms a jump discontinuity—the shock.

Once a discontinuity forms, the solution is no longer a globally differentiable function; thus, the sense in which it can be considered as a solution of the PDE must be clarified. A discontinuous function $(u(x, t))$ can still be considered as a solution in the weak sense if it satisfies

$$\iint_D \left(u \varphi_t + \frac{1}{2} u^2 \varphi_x \right) dx dt = 0, \quad (3)$$

where D is any rectangle in the (x, t) plane, and $\varphi(x, t)$ is any smooth function vanishing on the boundary ∂D . Any regular solution is a weak solution, as is seen by

multiplying the equation by $\varphi(x, t)$, integrating by parts along ∂D , and using Green's theorem.

In physical applications, one often considers the discontinuous solution as the limit, as $\mu \rightarrow 0$, of smooth solutions of the viscous Equation (1). This idea is correct from a physical point of view, as it takes into account the significance of these solutions as a physical description of gas dynamics. From the form of the equation (or its weak formulation (3)), one can derive the velocity v_s of a shock separating two regimes, u_r to the right and u_l to the left of a discontinuity. The result is the Rankine–Hugoniot formula, valid in general for conservation laws, which for the case of the Burgers equation yields

$$s = \frac{1}{2}(u_r + u_l). \quad (4)$$

Even this, however, is not enough to guarantee uniqueness of the solution, because there are several ways of writing the equation in the form of a conservation law. Often, the way to select the physically relevant solution is to consider the vanishing viscosity limit. To obtain this solution mathematically, an additional entropy condition, that $u_l > s > u_r$, must be imposed.

Besides its significance as a model for shocks, the Burgers equation is prominent among PDEs because it is completely integrable. Indeed, the nonlinear change of variable

$$u = -\mu(\log \psi)_x \quad (5)$$

transforms Equation (1) into the heat equation $\psi_t = \psi_{xx}$, with initial conditions transforming simply into initial conditions for this latter equation: if $u(x, 0) = f(x)$ is the given condition, then the corresponding initial condition for the heat equation is given by

$$\psi(x, 0) = \exp \left[-\frac{1}{\mu} \int_0^x f(\xi) d\xi \right].$$

The relation between the Burgers and the heat equation was already mentioned in an earlier book (Forsyth, 1906), but the former had not been recognized as physically relevant; hence, the importance of this connection was seemingly not noticed at the time. Using the transformation of Equation (5), known as the Cole–Hopf transformation, it is easy to solve the initial value problem for this equation. Recently, a generalization of the Cole–Hopf transformation has been successfully used to linearize the boundary value problem for the Burgers equation posed on the semiline $x > 0$ (Calogero & De Lillo, 1989).

The existence of this linearizing transformation, which is a transformation of Bäcklund type (Rogers & Shadwick, 1982) relating the solutions of two different PDEs, stimulated work to extend this approach to a generalized version of the Burgers equation, such as the Korteweg–de Vries–Burgers equation, given by

$$u_t + uu_x = \frac{\mu}{2} u_{xx} - \varepsilon u_{xxx}, \quad \varepsilon > 0. \quad (6)$$

Although it was found out that such a directly linearizing transformation did not exist, efforts in this direction were rewarded by several discoveries. Indeed, the importance of a linearizing transformation became evident when the inverse scattering transform (IST) was discovered, leading to the full analytical understanding of the solution of the Cauchy problem for the Korteweg–de Vries (KdV) equation, and later all integrable evolution equations in one spatial dimension, such as KdV, the nonlinear Schrödinger, and the sine-Gordon equations.

A crucial step in the discovery of the IST was an observation made by Robert Miura. In analogy to gas dynamics, he noted that one needs conservation laws to compute jump conditions across the region where the solution is small and essentially dispersive, isolating the solitonic part, which is thought of as a kind of reversible shock. This led to the connection between the KdV and modified KdV equation via the Miura transformation and eventually to the IST through which these nonlinear equations are solved through a series of linear problems (Gardner et al., 1967).

Nowadays, the Burgers equation is used as a simplified model of a kind of hydrodynamic turbulence (Case & Chiu, 1969), called Burgers turbulence. Burgers himself wrote a treatise on the equation now known by his name (Burgers, 1974), where several variants are proposed to describe this particular kind of turbulence. Generalizations such as the KdV–Burgers equation (6) arose from the need to model more complicated physical situations and introduce more factors than those that the Burgers equation takes into account. Lower-order friction terms may be considered that reduce the amplitude of the wave, although in a different scale and manner than the reduction due to the higher-order diffusion term u_{xx} . For example, the KdV–Burgers equation is an appropriate model when a different higher-order amplitude-reducing effect, namely dispersion, is introduced. Depending on the relative sizes of μ and ϵ , this equation may exhibit either an essentially shock-like structure, with the presence of dispersive tail, or mainly dispersive phenomena; thus, Equation (6) has been proposed as a natural model for hydrodynamic turbulence. In the context of the study of gas dynamics (particularly turbulent and vorticity phenomena), the Burgers equation has also been used to model phase diffusion along vortex filaments.

BUTTERFLY EFFECT

The Butterfly Effect serves as a metaphor for what in technical language is called “sensitive dependence on initial conditions” or “deterministic chaos,” the fact that small causes can have large effects.

As recounted by Gleick (1987, Chapter 1), in the early 1960s, Edward Lorenz was carrying out computer simulations on a 12-dimensional weather model. One day, he decided to run a particular time series for longer. In order to save time, he restarted his code from data from a previous printout. After returning from a coffee break, he found that the weather simulation had diverged sharply from that of his earlier run. After some checks, he could only conclude that the difference was caused by the difference in initial conditions: he had typed in only the first three of the six decimal digits that the computer worked with internally. Apparently, his assumption that the fourth digit would be unimportant was false.

Lorenz realized the importance of his observation: “If, then, there is any error whatever in observing the present state—and in any real system such errors seem inevitable—an acceptable prediction of an instantaneous state in the distant future may well be

impossible" (Lorenz, 1963, p. 133). Indeed, the error made by discarding the fourth and higher digits is so small that it can be imagined to represent the effect of the flap of the wings of a butterfly. Lorenz originally used the image of a seagull. The more lasting name seems to have come from his address at the annual meeting of the American Association for the Advancement of Science in Washington, December 29, 1972, which was entitled "Predictability: does the flap of a butterfly's wings in Brazil set off a tornado in Texas?" The text of this talk was never published but is presented in its original form as an appendix in Lorenz (1993).

Sensitive dependence on initial conditions forces us to distinguish between determinism and predictability, two concepts often confused by scientists and popular writers alike. Determinism has to do with how Nature (or, less ambitiously, any system under consideration) behaves, while predictability has to do with what we, human beings, are able to observe, analyze, and compute. We have determinism if we have a law or a formula describing exactly, and fully, how the system behaves given its present state. To have predictability we need, in addition, to be able to measure the present state of the system with sufficient precision and to compute with the given formula (to solve the equations) in a sufficiently accurate computational scheme.

Determinism is most famously expressed by Pierre-Simon Laplace (1814, p.2):

An intelligence that, at a given instant, could comprehend all the forces by which nature is animated and the respective situation of the beings that make it up, if moreover it were vast enough to submit these data to analysis, would encompass in the same formula the movements of the greatest bodies of the universe and those of the lightest atoms. For such an intelligence nothing would be uncertain, and the future, like the past, would be open to its eyes.

Laplace's dramatic statement is often erroneously interpreted as a belief in perfect predictability now rendered untenable by the chaos theory. But he was describing determinism: given the state of the system (the universe) at some time, we have a formula (a set of differential equations) that gives, in principle, the state of the system at any later time. Nowhere will one find a claim about the computability, by us humans, of all the consequences of the laws of mechanics. Indeed, the quote appears in the introduction of a book on probability. Laplace is, in fact, assuming incomplete knowledge from the start and uses probabilities to make rational inferences. If it were not for quantum mechanics, Laplace's statement would still stand, unaffected by deterministic chaos.

To illustrate the problems with computability, consider the simple but important example of the (deterministic) Bernoulli shift map defined by

$$f : [0, 1] \rightarrow [0, 1] : x_{n+1} = 2x_n \pmod{1}.$$

On numbers in binary representation, this map has a particularly simple effect: shift the binary point one place to the right and discard the first digit. For example, if $x_0 = 0.10110$ (which corresponds to the decimal 0.6875), then $x_1 = 0.01100$ (decimal 0.375). Now, any rational starting number x_0 is represented by a repeating sequence of 0s and 1s and hence leads to a periodic orbit of f , while any irrational x_0 is represented by a nonrepeating sequence of 0s and 1s and hence leads to a nonperiodic orbit. This latter sequence would appear as unpredictable as the sequence of heads and tails generated by flipping a coin, the quintessentially random process. Since there is an irrational number arbitrarily close to every rational number and vice versa, the map exhibits a sensitive dependence on initial conditions. In practice, on a computer, numbers are always represented with finite precision; hence, the computations become completely meaningless once—after a finite number of iterations—all significant digits have been removed. In the standard 32-bit (4-byte) floating point arithmetic with 23-bit mantissa, this will be after roughly 23 iterations.

The significance of the Bernoulli shift map is that dynamical systems theory tells us that its dynamics lies at the heart of the so-called "horseshoe dynamics," which in turn is commonly found in (the wide class of) systems with homoclinic (i.e., expanding and reinjecting) orbits (Wiggins, 1988). It means that in many situations, all we can say about a system's dynamics is of a statistical nature. A quantitative measure of the sensitivity on initial conditions, and therefore a measure of the predictability horizon, is provided by the leading Lyapunov exponent.

The possibility of small causes having large effects (in a perfectly deterministic universe) was anticipated by many scientists before Lorenz, and even before the birth of dynamical systems theory, which is generally accepted to have its origins in Poincaré's work on differential equations toward the end of the 19th century. Maxwell (1876, p. 20) wrote: "There is a maxim which is often quoted, that 'The same causes will always produce the same effects.'" After discussing the meaning of this principle, he adds: "There is another maxim which must not be confounded with [this], which asserts that 'Like causes produce like effects.'" This is only true when small variations in the initial circumstances produce only small variations in the final state of the system." He then gives the example of how a small displacement of railway points sends a train on different courses.

Others have often used the image of the weather:

Wiener (1954/55):

It is quite conceivable that the general outlines of the weather give us a good, large picture of its course for hours or possibly even for days. However, I am profoundly skeptical of the unimportance of the unobserved part of the weather for longer periods.

To assume that these factors which determine the infinitely complicated pattern of the winds and the temperature will not in the long run play their share in determining major features of weather, is to ignore the very real possibility of the self-amplification of small details in the weather map. A tornado is a highly local phenomenon, and apparent trifles of no great extent may determine its exact track. Even a hurricane is probably fairly local where it starts, and phenomena of no great importance there may change its ultimate track by hundreds of miles.

Poincaré (1908, p. 67):

Why have meteorologists such difficulty in predicting the weather with any certainty? Why is it that showers and even storms seem to come by chance, so that many people think it quite natural to pray for rain or fine weather, though they would consider it ridiculous to ask for an eclipse by prayer? We see that great disturbances are generally produced in regions where the atmosphere is in unstable equilibrium. The meteorologists see very well that the equilibrium is unstable, that a cyclone will be formed somewhere, but exactly where they are not in a position to say; a tenth of a degree more or less at any given point, and the cyclone will burst here and not there, and extend its ravages over districts it would otherwise have spared. If they had been aware of this tenth of a degree, they could have known it beforehand, but the observations were neither sufficiently comprehensive nor sufficiently precise, and that is the reason why it all seems due to the intervention of chance.

Even earlier, Franklin (1898, p. 173) had used an analogy surprisingly similar to Lorenz's:

... an infinitesimal cause may produce a finite effect. Long range detailed weather prediction is therefore impossible, and the only detailed prediction which is possible is the inference of the ultimate trend and character of a storm from observations of its early stages; and the accuracy of this prediction is subject to the condition that the flight of a grasshopper in Montana may turn a storm aside from Philadelphia to New York!

Duhem (1954, p. 141) used Hadamard's theorem of 1898 on the complicated geodesic motion on surfaces of negative curvature to "expose fully the absolutely irremediable physical uselessness of certain mathematical deductions." If such incomputable behavior is possible in mechanics, "the least complex of physical theories," Duhem goes on to ask rhetorically, "Should we not meet that ensnaring conclusion in a host of other, more complicated problems, if it were possible to analyse the solutions closely enough?"

Many had contemplated the possibility of sensitive dependence on initial conditions, but Lorenz was the first to see it actually happening quantitatively in the numbers spit out by his Royal McBee computing machine, and to be sufficiently intrigued by it to study it more closely in the delightfully simple system of equations now bearing his name (Lorenz, 1963). Indeed, while most scientists, with Duhem, had looked to complicated systems for unpredictable behavior, Lorenz found it in simple ones and thereby made it amenable to analysis.

CANDLE

At about the time that John Scott Russell was systematically studying hydrodynamic solitons on a Scottish canal, Michael Faraday, the brilliant English experimental physicist and physical chemist, organized his annual Christmas Lectures on facets of natural philosophy for young people. These included a series on the candle that began with the claim (Faraday, 1861):

There is no better, there is no more open door by which you can enter into the study of natural philosophy than by considering the physical phenomena of a candle.

Although this assertion may have startled some of his listeners, Faraday went on to support it with a sequence of simple yet elegant experiments that clearly expose the structure and composition of a candle flame, demonstrating a stream of energy-laden vapor feeding into the flame and suggesting an analogy with the process of respiration in living organisms (Day & Catlow, 1994). (An engraving showing Faraday presenting one of these lectures can be found on a recent British 20-pound note.)

While the details are intricate (Fife, 1988), the flame of a candle can be regarded globally as a dynamic process balancing two flows of energy: the rate at which energy is dissipated by the flame (through emission of heat and light) and the rate at which energy is released from the wax as the flame eats its way down the candle. Let us define variables as follows.

- P is the power dissipation by the flame, in units of (say) joules per hour.
- E is the chemical energy stored in the wax of the candle, in units of (say) joules per centimeter.
- v is the speed at which the flame moves down the candle.

If the rates of dissipation and energy input are equal, then the velocity of the flame is determined by the power

balance condition

$$P = vE, \quad (1)$$

implying $v = P/E$ (cm/h). Metaphorically, the flame must digest energy at the same rate at which it is eaten.

Consider a family of cylindrical candles with various diameters (d), and assume the dissipation rates of their flames to be independent of the sizes of the candles. Since stored chemical energy is proportional to the area of cross section ($E \propto d^2$), power balance implies

$$v \propto 1/d^2. \quad (2)$$

Some measured flame speeds for typical candles are plotted on a log–log scale in Figure 1, where the dashed line of slope -2 indicates a $1/d^2$ dependence. From this figure, it is evident that the inverse square dependence of Equation (2) is obeyed for larger candles. For smaller candles, v is somewhat less than expected, because the flames are not so large.

Although Equation (2) was derived for candles, Equation (1) is quite general, expressing a global constraint that governs the dynamics of many kinds of nonlinear diffusion, including the propagation of nerve impulses (Scott, 2002). For a smooth axon described by the Hodgkin–Huxley equations, power balance is established between electrostatic energy released from the fiber membrane and ohmic dissipation by circulating ionic currents, implying $v \propto \sqrt{d}$. (Plotted in Figure 1, this dependence would have a slope of $+\frac{1}{2}$.) For myelinated nerves, on the other hand, evolutionary pressures require that $v \propto d$, corresponding to a slope of unity in Figure 1.

In the language of nonlinear dynamics, a candle flame provides a physical example of an attractor, which is evidently stable because moderate disturbances (small gusts of air) do not extinguish the flame by forcing it out of its basin of attraction. As the air becomes still, the flame returns to its original shape and size. The task of lighting a candle, on the other hand, requires getting the wick hot enough—above an

Figure 1. Measurements of flame speeds (v) for candles of different diameters (d). The error bars indicate rms deviations of about six individual measurements. (Data courtesy of Lela Scott MacNeil Scott (2003).)

ignition threshold and into the basin of attraction—so that a viable flame is established. Qualitatively similar conditions govern the firing of a nerve axon, leading to an all-or-nothing response.

From a more intuitive perspective, an ignition threshold implies the power balance indicated in Equation (1), where the corresponding flame is unstable. Above the threshold, instability arises from the establishment of a positive feedback loop, in which the flame releases more than enough chemical energy than is needed to maintain its temperature. Such a positive feedback loop is represented by the diagram

with the gain about the loop being greater than unity, implying an increase in the flame size with time (Scott, 2003). Eventually, this temporal increase is limited by nonlinear effects in the release and dissipation of energy, reducing the loop gain to unity as the fully developed flame is established.

The candle flame is an example of a reaction-diffusion (or autocatalytic) process, going back to an early suggestion by Robert Luther, a German physical chemist (Luther, 1906). Following a lecture demonstration of a chemical wave, Luther claimed that such systems should support traveling waves at a speed proportional to $\sqrt{D/\tau}$ where D is the diffusion constant for the reacting components (in units of distance squared per unit of time) and τ is a delay time for the onset of the reaction. During the 1930s, autocatalytic systems were studied in the context of genetic diffusion through spatially dispersed biological species, and in

1938 the equation

$$D \frac{\partial^2 u}{\partial x^2} - \frac{\partial u}{\partial t} = \frac{1}{\tau} u(u-a)(u-1), \quad (3)$$

where a is a threshold parameter lying in the range $(0, \frac{1}{2}]$, was used by Soviet scientists Yakov Zeldovich and David Frank-Kamenetsky to represent a flame front. These authors showed that uniform traveling waves solutions of Equation (3) propagate at a fixed speed given by the expression

$$v = (1-2a)\sqrt{D/2\tau}, \quad (4)$$

which includes both Luther's factor $(\sqrt{D/\tau})$ and the power balance condition. Long overlooked by the neuroscience community, this early work on flame propagation offers a convenient model for the leading edge of a nerve impulse, confirming Faraday's intuition (Scott, 2002).

CARDIAC ARRHYTHMIAS AND THE ELECTROCARDIOGRAM

In the early 1900s, Willem Einthoven developed the string galvanometer to measure the potential differences in the body surface associated with the heartbeat and introduced a nomenclature for the deflections of the electrocardiogram that are still used today. For this work, Einthoven was awarded a Nobel prize in 1924 (Katz & Hellerstein, 1964).

The electrocardiogram (ECG) is a measurement of the potential difference between two points on the surface of the body. Because the heart generates waves of electrical activation that propagate through the heart during the cardiac cycle, ECG measurements reflect cardiac activity. Over the past century, physicians have learned how to interpret the electrocardiogram to diagnose a variety of different cardiac abnormalities. Although interpreting an ECG is difficult, this entry introduces the basic principles.

In order to appreciate the ECG, it is first necessary to have a rudimentary knowledge about the spread of the cardiac impulse in the heart. The heart is composed of four chambers, the right and left atria, and the right and left ventricles (see Figure 1). The atria are electrically connected to each other, but are insulated from the ventricles everywhere except in a small region called the atrioventricular (AV) node. The ventricles are also electrically connected to each other. The rhythm of the heart is set by the sinoatrial node located in the right atrium, which acts as the pacemaker of the heart. From a mathematical perspective, this pacemaker is an example of a nonlinear oscillator. Thus, if the rhythm is perturbed, for example, by delivering a shock to the atria, then in general the timing of subsequent firings of the sinus node may be reset (i.e., they occur at different times than they would have if the shock had not been delivered), but the frequency and amplitude of the oscillation will remain the same. A wave of excitation initiated in the sinus node travels through the atria, then through the atrioventricular node, and then through specialized Purkinje fibers to the ventricles. The wave of electrical excitation is associated with a wave of mechanical contraction so that the cardiac cycle is associated with contraction and pumping of

the blood through the body. The right and left atria are comparatively small chambers and act as collection points for blood. The right atrium collects blood from the body and the left atrium collects blood from the lungs. The right ventricle pumps blood to the lungs to be oxygenated, whereas the left ventricle pumps blood that has returned to the heart from the lungs to the rest of the body. The right atrium and right ventricle are separated by the tricuspid valve that prevents backflow of blood during the ventricular contraction. Similarly, the left atrium and left ventricle are separated by the mitral valve. In order to pump the blood, the ventricles are comparatively large and muscular.

In the normal ECG, there are several main deflections labeled the P wave, the QRS complex, and the T wave, Figure 2a (Goldberger & Goldberger, 1994). The P wave is associated with the electrical activation of the atria, the QRS complex is associated with the electrical activation of the ventricles, and the T wave is associated with the repolarization of the ventricles. The duration of the PR interval reflects the conduction time from the atria to ventricles, which is typically 120–200 ms. The duration of the QRS complex reflects the time that it takes for the wave of excitation to activate the ventricles. Because of the specialized Purkinje fibers, the wave of activation spreads rapidly through the ventricles so that the normal duration of the QRS complex is less than 100 ms. The time interval from the beginning of the QRS complex to the end of the T wave, called the QT interval, reflects the time that the ventricles are in the contraction phase. The

Figure 2. Sample electrocardiograms. In all traces, one large box represents 0.2 s. (a) The normal electrocardiogram. The P wave, QRS complex, and T wave are labeled. (b) 3:2 Wenckebach rhythm, an example of a second-degree heart block. There are 3 P waves for each R wave in a repeating pattern. (c) Parasystole. The normal beats, labeled N, occur with a period of about 790 ms, and the abnormal ectopic beats, labeled E, occur with a regular period of 1300 ms. However, when ectopic beats fall too soon after the normal beats, they are blocked. Normal beats that occur after an ectopic beat are also blocked. If a normal and ectopic beat occur at the same time, the complex has a different geometry, labelled F for fusion. In this record, the number of normal beats occurring between ectopic beats is either 4, 2, or 1, satisfying the rules given in the text. Panels (a) and (b) are adopted from Goldberger & Goldberger (1994), with permission. Panel (c) is adapted from Courtemanche et al. (1989) with permission.

duration of QT interval depends somewhat on the basic heart rate. It is shorter when the heart is beating faster. For heart beats in the normal range, the QT interval is typically of the order of 300–450 ms.

On examining an ECG, one first looks for P waves. The presence of the P wave indicates that the heart beat is being generated by the normal pacemaker. In the normal heart, each P wave is followed by a QRS complex and then a T wave. The heart rate is often measured by time intervals between two consecutive R waves. Abnormally fast heart rates, faster than about 90 beats per minute, are called tachycardia, and abnormally slow heart rates, slower than about 50 beats per minute, are called bradycardia.

Reduced to the basics, all cardiac arrhythmias (i.e., abnormal cardiac rhythms) are associated with abnormal initiation of a wave of cardiac excitation, abnormal propagation of a wave of cardiac excitation, or some combination of the two. Given such a simple underlying concept, it is not surprising that mathematicians have been attracted to the study of cardiac arrhythmias, or that many cardiologists are mathematically inclined. However, despite the apparent simplicity, cardiac arrhythmias can manifest themselves in many different ways, and it is still not always possible to figure out the mechanism of an arrhythmia in any given individual. The following is focused on some arrhythmias that are well understood and that have interesting mathematical analyses.

One class of cardiac arrhythmias is associated with conduction defects through the AV node. In first-degree heart block, the PR interval is elevated above its normal value, but each P wave is followed by a QRS complex and T wave. However, in second-degree heart block, there are more P waves than QRS complexes, as some of the atrial activations do not propagate to the ventricles. This type of cardiac arrhythmia, sometimes called Wenckebach rhythms (after Karel Frederik Wenckebach, a Dutch-born Austrian physician, who studied these rhythms at the beginning of the 20th century), has repeatedly attracted theoretical interest (Katz & Hellerstein, 1964). It is common to classify Wenckebach rhythms by a ratio giving the number of P waves to the number of QRS complexes. For example, Figure 2b shows a 3:2 heart block.

In the 1920s, Balthasar van der Pol and J. van der Mark developed a mathematical model of the heart as coupled nonlinear oscillators that displayed striking similarities to the Wenckebach rhythms. We now understand that in a number of different models, as the frequency of atrial activation is increased, different types of $N:M$ heart block can be observed (van der Pol & van der Mark, 1928). In fact, theoretical models have demonstrated that if there is $N:M$ heart block at one stimulation frequency and an $N':M'$ heart block at a higher frequency, then the $N+N':M+M'$ heart block is expected at

some intermediate stimulation frequency. This result provides a mathematical classification complementary to the cardiological classification, and can be confirmed in clinical settings (Guevara, 1991). Finally, in third-degree heart block, there is a regular atrial rhythm and a regular ventricular rhythm (at a slower frequency), but there is no coupling between the two rhythms. Such rhythms in mathematics are called quasi-periodic.

A different type of rhythm that appeals to mathematicians is called parasystole. In the “pure” case, the normal sinus rhythm beats at a constant frequency, and an abnormal (ectopic) pacemaker in the ventricles beats at a second slower frequency (Glass et al., 1986; Courtemanche et al., 1989). Figure 2c shows the normal (N) beats and the ectopic (E) beats. If the ectopic pacemaker fires at a time outside the refractory period of the ventricles, then there is an abnormal ectopic beat, identifiable on the ECG by a morphology distinct from the normal beat, and the following normal sinus beat is blocked. If the normal and abnormal beats occur at the same time, this leads to a fusion (F) beat.

Surprisingly, this simple mechanism has amazing consequences that can be appreciated by forming a sequence of integers that counts the number of sinus beats between two ectopic beats. In general, for fixed sinus and ectopic frequencies and a fixed refractory period, in this sequence, there are at most three integers, where the sum of the two smaller integers is one less than the largest integer. Moreover, given the values of the parameters, it is possible to predict the three integers. The mathematics for this problem is related to the “gaps and steps” problem in number theory. Both AV heart block and parasystole lead to mathematical predictions of cardiac arrhythmias in humans, which have been tested in experimental models and in humans. Such arrhythmias are diagnosed and treated when necessary, by physicians who have no knowledge of the underlying mathematics. Thus, to date, the mathematical analysis of these arrhythmias is of little medical interest.

From a medical perspective, the most important class of arrhythmias is called re-entrant arrhythmias. In these arrhythmias, the period of the oscillation is set by the time an excitation takes to travel in a circuitous path, rather than the period of oscillation of a pacemaker. The re-entrant circuit can be found in a single chamber of the heart or can involve several anatomical features of the heart (Josephson, 2002). In typical atrial flutter, there is a wave circulating around the tricuspid valve in the right atrium; in Wolf–Parkinson–White syndrome, there can be excitation traveling in the normal circuit from atria to the AV node to the ventricles, but then traveling retrogradely back to the atria via an abnormal accessory pathway between the ventricles and the atria. Also in some patients who have had a heart attack, there is a re-entrant circuit contained entirely in the ventricles. In all these three re-entrant arrhythmias, a

part of the circuit is believed to be a comparatively thin strand of tissue.

Considering these re-entrant arrhythmias from a mathematical perspective, the wave often appears to be circulating on a one-dimensional ring. This conceptualization developed by cardiologists has an important implication for therapy: "if you cut the ring, you can cure the rhythm." By inserting catheters directly into a patient's heart and delivering radio frequency radiation to precisely identified loci, the cardiologist destroys heart tissue and can often cure these serious arrhythmias. In these cases, the cardiologist is thinking like a topologist since changing the topology of the heart cures the arrhythmia. Moreover, there is a body of mathematics that has studied the properties of excitation traveling on one-dimensional rings (Glass et al., 2002).

Other reentrant arrhythmias are not as well understood and are not as easily treated. Many theoretical and experimental studies (See **Cardiac muscle models**) have documented spiral waves circulating stably in two dimensions and scroll waves circulating in three dimensions (Winfree, 2001). Since real hearts are three-dimensional, and there is still no good technology to image excitation in the depth (as opposed to the surface) of the cardiac tissue, the actual geometry of excitation waves in cardiac tissue associated with some arrhythmias is not as well understood and is now the subject of intense study.

From an operational point of view, it is suggested that any arrhythmia that cannot be cured by a small localized lesion in the heart is a candidate for a circulating wave in two or three dimensions. Such rhythms include atrial and ventricular fibrillation. In these rhythms, there is evidence of strong fractionation (breakup) of excitation waves giving rise to multiple small spiral waves and patterns of shifting blocks. Tachycardias can also arise in the ventricles in patients other than those who have experienced a heart attack, or perhaps occasionally in hearts with completely normal anatomy, and in these individuals it is likely that spiral and scroll waves are the underlying geometries of the excitation. A particularly dangerous arrhythmia, polymorphic ventricular tachycardia (in which there is a continually changing morphology of the ECG complexes), is probably associated with spiral and scroll waves that undergo a meander. New technologies are presenting unique opportunities to image cardiac arrhythmias in model systems and the clinic, and nonlinear dynamics is suggesting new strategies for controlling cardiac arrhythmias. For a summary of advances up until 2002 see the collection of papers in Christini & Glass (2002).

Despite the great advances in research and medicine over the past 100 years, there is still a huge gap between what is understood and what actually happens in the human heart. The only way to appreciate this gap is to

toss out the models and start looking at real data from patients who are experiencing complex arrhythmias as measured on the ECG. All who plan to model cardiac arrhythmias are encouraged to take this step.

CARDIAC MUSCLE MODELS

Cardiac muscle was created by evolution to pump the blood, and contractions of cardiac muscle, as of any muscle, are governed by calcium (Ca) ions. Increased concentration of calcium ions inside a cardiac cell ($[Ca]_i$) induces a contraction, and diminished concentration induces relaxation (diastole). Calcium ion concentration in a cardiac cell is governed by many mechanisms. Importantly, a signal to increase $[Ca]_i$ is given by an abrupt increase in membrane potential E , which is called an action potential (AP). The membrane potential E in cardiac cells is described by reaction diffusion equations.

Cardiac models have the mathematical structure of the well-known Hodgkin–Huxley (HH) equations:

$$\partial E / \partial t = -I(E, g_1, \dots, g_N) / C + \nabla \cdot (\mathbf{D} \nabla E), \quad (1)$$

$$\partial g_i / \partial t = (\tilde{g}_i(E) - g_i) / \tau_i(E), \quad i = 1, \dots, N, \quad (2)$$

where g_i are the gating variables (describing opening and closing of the gates of ionic channels), $\bar{g}_i(E)$ are the steady values of those variables, $\tau_i(E)$ are associated time constants, $I(\cdots)$ is the transmembrane ionic current, and the diffusive term $\nabla \cdot (D \nabla E)$ describes the current flowing from the neighboring cells. In this description of the coupling, the anisotropy of the heart is properly described with an anisotropic diffusivity tensor. Equations (1) and (2) are similar to standard HH equations (with $N = 3$), and this formulation was used for the first cardiac model introduced by Denis Noble in 1962. As more and more ionic channels were discovered, they were incorporated into more detailed models: $N = 6$ for a modified Beeler–Reuter (BR) model, and $N > 10$ for the Luo–Rudy model and for recent Noble models. Although the original HH formulation was based on analytic functions for the $\bar{g}_i(E)$ and $\tau_i(E)$, experimentally measured functions can be used in the equations, as shown in Figure 1. This results in both physical transparency and faster numerical calculations.

The functions $g_i(E)$ and $\tau_i(E)$ have a simple physical interpretation—the dynamics of each gating variable g_i are governed by the membrane potential E only. For fixed E , Equations (2) are linear and independent; each of them describes relaxation to the steady value $\bar{g}_i(E)$ with the time constant $\tau_i(E)$. The characteristic times $\tau_i(E)$ span four orders of magnitude (see Figure 1(a)), leading to qualitative understanding using time-scale separation.

Figure 1. BR model with eight variables. (a) Gating variables $\bar{g}_i(E)$. (b) Time constants $\tau_i(E)$ (log scale).

Noble's 1962 Model

This original cardiac model (N4 model), which is the key for understanding all subsequent models, consists of the following four equations (Noble, 1962).

$$\partial E / \partial t = -(I_{Na}(E, m, h) + I_K(E, n)) / C + D \nabla^2 E, \quad (3)$$

$$\partial n / \partial t = (\bar{n}(E) - n) / \tau_n, \quad (4)$$

$$\partial m / \partial t = (\bar{m}(E) - m) / \tau_m, \quad (5)$$

$$\partial h / \partial t = (\bar{h}(E) - h) / \tau_h, \quad (6)$$

where

$$I_{Na}(E, m, h) = (g_{Na} m^3 h + \varepsilon_1)(E - E_{Na}), \quad (7)$$

$$I_K(E, n) = (\alpha g_K n^4 + \varepsilon_2)(E - E_K), \quad (8)$$

A cardiac action potential has a duration of about 200 ms, which is about two orders of magnitude longer than that of a typical nerve impulse. To describe cardiac action potential, just one time constant in the HH equations was increased by a factor of 100, two small terms (ε_1 and ε_2) were added, and other time constants were adjusted to incorporate cardiac experimental results.

To observe how the N4 model works, note that it has three gating variables: m , n , and h . The characteristic time τ_n is about 100 ms, while τ_m and τ_h are almost two orders of magnitude faster (shorter). This permits adiabatic elimination of the fast equations (5) and (6), thereby replacing Equations (3)–(6) with a system of equations only (system N2) (Krinsky & Kokoz, 1973):

$$\partial E / \partial t = -(I_{Na}(E, \bar{m}, \bar{h}) + I_K(E, n)) / C + D \nabla^2 E, \quad (9)$$

$$\partial n / \partial t = (\bar{n}(E) - n) / \tau_n. \quad (10)$$

Note that the current I_{Na} becomes

$$I_{Na} = (g_{Na} \bar{m}^3(E) \bar{h}(E) + \varepsilon_1)(E - E_{Na}), \quad (11)$$

which contains only the known functions $\bar{m} \equiv \bar{m}(E)$ and $\bar{h} \equiv \bar{h}(E)$. The behavior of this model is illustrated in Figure 2.

Nullclines $dE/dt = 0$, and $dn/dt = 0$ for a Purkinje fiber are shown in Figure 2(a). A Purkinje fiber has a pacemaker activity, which the nullclines (in the phase plane) show directly. Note that there is only one fixed point S, which is unstable, thus giving rise to limit cycle oscillations.

The nullclines for a myocyte are shown in Figure 2(b). There is no pacemaker activity in myocytes; thus, the nullclines show the absence of a limit cycle. Although there are two unstable fixed points (S' and S''), they do not induce a limit cycle because there is a third fixed point (S) that is stable and determines the resting potential.

2003) is also available at <http://www-binf.bio.uu.nl/khwjtuss/HVM>.

In contemporary models the gap between the 100 and 1 ms time scales has been filled by many ionic currents, and (contrary to what was seen in the first cardiac model) the graphs even intersect each other (see Figure 1(b)). This makes the separation for fast and slow variables dependent upon the phase of AP, so results as in Figure 2 cannot be obtained directly. Instead, events on every time scale must be analyzed separately, eliminating adiabatically equations with a faster time scale and considering variables with a larger time scale fixed, or even postulating a model with only two to four equations (Keener & Sneyd, 1998; Fenton & Karma, 1998).

Models that do not follow the HH formalism are needed because HH-type models predict that a point stimulation will create a circular or an elliptical distribution of membrane potential, while in the experiments a quadrupolar distribution was found. Thus, *bidomain models* were created that describe separately potentials inside (E_i) and outside (E_o) of a cell instead of considering $E_o=0$ as in the HH formulation. These models correctly reproduce many important electrophysiological effects, and turn out to be useful for understanding the mechanisms of cardiac defibrillation (Trayanova et al., 2002). The integration of these models, however, is computationally more expensive than the integration of HH models. *Markov chain models* are used to describe transitions between states of single ionic channels linking genetical defects with cardiac arrhythmias. They also depart from the HH formalism. *Anatomical models* incorporate cardiac geometry and tissue structure, but they require months of laborious measurements on anatomical slices cut from the heart. A new approach is being developed at INRIA in France, which aims to create models for every cardiac patient and is intended to be used in clinics. Cardiac contractions are measured and incorporated into the model. NMR tomography methods were used that permit obtaining anatomical data in a few minutes, not months, see <http://www-sop.inria.fr/epidaur/>. More cardiac models and authors can be found at <http://www.cardiacsimulation.org/>.

Dynamics of Myocardial Tissue

In the past, breakthroughs were due to very simple models beginning with the pioneering work of Norbert Wiener and Arturo Rosenbluth (Wiener & Rosenbluth, 1946). They led the way to understanding rotating waves using a cellular automata model, where a cardiac cell can be in three states only: rest, excitation, and refractory. This model explained anatomical reentry (a wave rotating around an obstacle (Wiener & Rosenbluth, 1946)), and predicted a free rotating wave. Partial differential equations yield more refined refined results (Keener & Sneyd, 1998).

As two- and three-dimensional studies of rotating waves are time consuming, it is often convenient to use a two-variable model, permitting increased speed of calculations by two orders of magnitude. Numerical simulation of ionic models can be accelerated either by adiabatic elimination of fast variable m (Na) activation or by slowing down its dynamics and increasing the diffusion coefficient to keep the propagation velocity unchanged.

Propagation Failure

As cardiac cells are connected via gap junctions, an excitation can be blocked when propagating from one cardiac cell to another, similar to the propagation failure in myelinated nerves. When an excitation propagates from auricles (A) to ventricles (V) via the AV node, a periodic pattern can be observed: for example, from every three pulses, only two pulses propagate, and the third pulse is blocked (3:2 Wenckebach periodicity). Other periodicities $N : (N - 1)$ can also be observed. Propagation block can be observed on any cardiac heterogeneity when the period T of stimulation is shorter than the restoration time R (refractory period). Usually, Wenckebach rhythms with only small periods N are observed because

$$T_N \sim N^{-2}, \quad (13)$$

where T_N is an interval of T that can yield. Wenckebach rhythms with period N . When an excitation block (Wenckebach rhythm) occurs in a two- or three-dimensional excitable medium, it generically gives rise to a wave break that evolves into a rotating wave. For cardiac muscle, initiation of a rotating wave is a dangerous event, often leading to life-threatening cardiac arrhythmias.

A new approach is being developed at INRIA in France, to create patient-specific models to be used in clinics. A 3-d electro-mechanical model of the heart is automatically adapted to a time series of volumetric cardiac images gated on the ECG (Ayache et al., 2001) providing useful quantitative parameters on the heart function in a few minutes, not months, see <http://www-sop.inria.fr/epidaur/>.

CAT MAP

The cat map is perhaps the simplest area-preserving transformation that exhibits a high degree of chaos. In the development of the theory of dynamical systems, it served as a guiding example to illustrate new concepts such as entropy (Sinai, 1959) and Markov partitions (Adler & Weiss, 1967). The cat map owes its name to an illustration by V.I. Arnol'd showing the image of a cat before and after the application of the map. In the mathematical literature it is also referred to as “hyperbolic toral automorphism.”

The torus M , which topologically has the shape of a doughnut, may be described by the points in the unit square (see Figure 1) where opposite sides are identified. Alternatively, one may think of a point on M as a point in the plane $\mathbb{R}^2$ modulo integer translations in $\mathbb{Z}^2$. This yields a representation of M as the coset space $\mathbb{R}^2/\mathbb{Z} := \{x + \mathbb{Z}^2 : x \in \mathbb{R}^2\}$. The cat map is now

a mapping $\phi : M \rightarrow M$ defined by $x \mapsto Ax \pmod{\mathbb{Z}^2}$, where

$$x = \begin{pmatrix} x_1 \\ x_2 \end{pmatrix}, \quad A = \begin{pmatrix} a & b \\ c & d \end{pmatrix}, \quad (1)$$

provided $a, b, c, d \in \mathbb{Z}$ are chosen such that $|\det A| = 1$ and A has eigenvalues $\lambda_{\pm}$ with modulus not equal to one. (This implies that both eigenvalues are real and distinct.) The matrix A used in our illustration is

$$A = \begin{pmatrix} 2 & 1 \\ 1 & 1 \end{pmatrix}. \quad (2)$$

Let us now explore some of the dynamical properties that show that the cat map is indeed completely “chaotic” (See **Chaotic dynamics**). Sensitivity on initial conditions is measured by the rate of divergence of two nearby points, x and $x + \delta x$, under iterations of ϕ . For any smooth map ϕ , the Taylor expansion for small δx yields $\phi(x + \delta x) = \phi(x) + D\phi_x \delta x + O(\delta x^2)$ where $D\phi_x$ is the differential of ϕ at x ; it may be viewed as a linear map from TM_x to $TM_{\phi(x)}$, the tangent spaces at x and $\phi(x)$, respectively.

Because ϕ is linear in the case of the cat map, the above Taylor expansion is in fact exact, that is, $\phi(x + \delta x) = \phi(x) + D\phi_x \delta x$ with $D\phi_x = A$. If $v_{\pm}$ are the eigenvectors of A corresponding to the eigenvalues $\lambda_{\pm}$, let us denote by E_x^+ and E_x^- the subspaces of TM_x spanned by v_+ and v_- , respectively. As $\lambda_+ \neq \lambda_-$, we have

$$TM_x = E_x^+ \oplus E_x^-. \quad (3)$$

Furthermore, since $|\lambda_+| = 1/|\lambda_-| > 1$, we find

$$\|D\phi_x(\xi)\| \geq e^{\lambda} \|\xi\| \quad \text{if } \xi \in E_x^+, \quad (4)$$

$$\|D\phi_x(\xi)\| \leq e^{-\lambda} \|\xi\| \quad \text{if } \xi \in E_x^-, \quad (5)$$

where $\lambda = \ln |\lambda_+| > 0$ and $\|\cdot\|$ is the Euclidean norm. Hence, ϕ is expanding in the direction of v_+ , and contracting in the direction of v_- , which will therefore be referred to as the unstable and stable directions, respectively. [Here, inequalities (4) and (5) are in fact equalities; inequalities become necessary in the case of more general Anosov maps, if one seeks uniform bounds with λ independent of x .] For the n th forward or backward iterates of the map (n a positive integer), we have, by the above arguments with ϕ replaced by $\phi^{\pm n}$,

$$\begin{aligned} \|D\phi_x^n(\xi)\| &\geq e^{n\lambda} \|\xi\|, & \|D\phi_x^{-n}(\xi)\| &\leq e^{-n\lambda} \|\xi\|, \\ \text{if } \xi &\in E_x^+, & & \end{aligned} \quad (6)$$

$$\begin{aligned} \|D\phi_x^n(\xi)\| &\leq e^{-n\lambda} \|\xi\|, & \|D\phi_x^{-n}(\xi)\| &\geq e^{n\lambda} \|\xi\|, \\ \text{if } \xi &\in E_x^-. & & \end{aligned} \quad (7)$$

Figure 1. The cat map: the image of a cat in the unit square (left) is stretched by the matrix A (middle) and then re-assembled by cutting and translating (without rotation) the different parts of the cat's face back into the unit square (right). (Illustration by Federica Vasetti.)

The expansion/contraction is thus exponentially fast in time. Relations (3), (6), and (7) are equivalent to the statement that the cat map is an Anosov system. Special features of Anosov systems are ergodicity, mixing, structural stability, exponential proliferation of periodic orbits, and positive entropy h .

There is a particularly simple formula for the entropy h due to Sinai (1959), which states that $h = \lambda = \ln |\lambda_+|$. The number of fixed points of the n th iterate ϕ^n is equal to $|\det(1 - A^n)| = |(1 - \lambda_+^n)(1 - \lambda_-^n)|$ and is therefore asymptotically given by $\exp(nh)$, for large n . The notion of ergodicity implies that for any $f \in L^1(M, dx)$, for almost every $x \in M$ (that is, for all x up to a set of Lebesgue measure zero), we have

$$\lim_{N \rightarrow \infty} \frac{1}{N} \sum_{n=0}^{N-1} f(\phi^n x) = \langle f \rangle, \quad \langle f \rangle := \int_M f(x) dx. \quad (8)$$

"Mixing" means that, if $f, g \in L^2(M, dx)$, then

$$\lim_{n \rightarrow \pm\infty} \int_M f(\phi^n x) g(x) dx = \langle f \rangle \langle g \rangle. \quad (9)$$

Although the mixing property follows from general arguments for Anosov systems, it can be proved for ϕ directly by means of Fourier analysis. What is more, the rate of convergence in (9) is in fact exponentially fast in n for suitably smooth test functions f, g ("exponential decay of correlations") and super-exponentially fast for analytic ones.

Markov partitions are a powerful tool in the analysis of dynamical systems. In the case of the cat map the torus is divided into a finite collection of non-overlapping parallelograms $P_1, \dots, P_N$ whose sides point in the directions of the eigenvectors v_+ and v_- , such that if $\phi(P_i)$ (or $\phi^{-1}(P_i)$) intersects with P_j , then it extends all the way across P_j . Let us construct an N by N matrix B whose coefficients are $B_{ij} = 1$ if the intersection of $\phi(P_i)$ with P_j is non-empty, and $B_{ij} = 0$ otherwise. A symbolic description of the

dynamics of the cat map can now be obtained as follows. Consider doubly infinite sequences of the form $\dots b_{-2}b_{-1}b_0b_1b_2\dots$, where b_n is an integer $1, \dots, N$ with the condition that the number b_n can be followed by b_{n+1} only if $B_{b_n b_{n+1}} = 1$. To each such sequence we can associate a point x on M by requiring that for every $n \in \mathbb{Z}$, the parallelogram R_{b_n} contain the iterate $\phi^n(x)$. The symbolic dynamics of ϕ is now given by shifting the mark by one step to the right: the new word $\dots b_{-1}b_0b_1b_2b_3\dots$ indeed represents the point $\phi(x)$. The dynamical properties of ϕ are thus encoded in the matrix B . In particular, the higher the rate of mixing of ϕ , the smaller the number of coefficients B_{ij} that are zero. This in turn means that we have fewer restrictions on $b_n \mapsto b_{n+1}$ and a typical orbit will be represented by a more "random" sequence of symbols.

Cat maps, as well as higher-dimensional toral automorphisms, are featured in most textbooks on dynamical systems and ergodic theory. An introduction to the basic concepts may be found in Arnol'd & Avez (1968), and more advanced topics, such as entropy, Markov partitions, and structural stability, are discussed, for example, in Adler & Weiss (1970), Katok & Hasselblatt (1995), Pollicott & Yuri (1998), and Shub (1987).

CATALYTIC HYPERCYCLE

The concept of the “hypercycle” was invented in the 1970s in order to characterize a functional entity that integrates several autocatalytic elements into an organized unit (Eigen, 1971; Eigen & Schuster, 1977, 1978a,b). This concept is a key to understanding the dynamics of living organisms.

A catalytic hypercycle is defined as a cyclic network of autocatalytic reactions (Figure 1). Autocatalysts, in general, compete when they are supported by the same source of energy or material. Hypercyclic coupling introduces mutual dependence of elements and suppresses competition. Consequently, the fate of all members of a hypercycle is identical to that of the entire system and, in other words, no element of a hypercycle dies out provided the hypercycle as such survives.

The current view of biological evolution distinguishes periods of dominating Darwinian evolution based on variation, competition, and selection interrupted by rather short epochs of radical innovations often called *major transitions* (Maynard Smith & Szathmáry, 1995; Schuster, 1996). In the course of biological evolution major transitions introduce higher hierarchical levels. Examples are (i) the origin of translation from nucleic acid sequences into proteins including the invention of the genetic code, (ii)

the transition from independent replicating molecules to chromosomes and genomes, (iii) the transition from the prokaryotic to the eukaryotic cell, (iv) the transition from independent unicellular individuals to differentiated multicellular organisms, (v) the transition from solitary animals to animal societies, and (vi) presumably a series of successive transitions from animal societies to humans. All major transitions introduce a previously unknown kind of cooperation into biology. The hypercycle is one of very few mechanisms that can deal with cooperation of otherwise competing individuals. It is used as a model system in prebiotic chemistry, evolutionary biology, theoretical economics, as well as in cultural sciences.

The simplest example of a catalytic hypercycle is the *elementary hypercycle*. It is described by the dynamical system

$$\frac{dx_i}{dt} = x_i \left(f_i x_{i-1} - \sum_{j=1}^n f_j x_{j-1} x_j \right);$$

$$i, j = 1, 2, \dots, n; i, j = \text{mod } n. \quad (1)$$

The catalytic interactions within a hypercycle form a directed closed loop comprising all elements, often called Hamiltonian arc: $1 \rightarrow 2 \rightarrow 3 \rightarrow \dots \rightarrow n \rightarrow 1$ (Figure 1). Hypercycles are special cases of replicator equations of the class

$$\frac{dx_i}{dt} = x_i \left(\sum_{j=1}^n a_{ij} x_j - \sum_{j=1}^n \sum_{k=1}^n a_{jk} x_j x_k \right);$$

$$i, j, k = 1, 2, \dots, n \quad (2)$$

with $a_{ij} = f_i \cdot \delta_{i-1,j}$; $i, j = \text{mod } n$. (The ‘mod n ’ function implies a cyclic progression of integers, $1, \dots, n-1, n, 1, \dots$. The symbol $\delta_{i,j}$ represents Kronecker’s symbol: $\delta = 1$ for $i = j$ and $\delta = 0$ for $i \neq j$.)

For positive rate parameters and initial conditions inside the positive orthant (the notion of an *orthant* refers to the entire section of a Cartesian coordinate system in which the signs of variables do not change. In n -dimensions, the positive orthant is defined by $\{x_i > 0 \ \forall i = 1, 2, \dots, n\}$). The trajectory of a hypercycle remains within the orthant:

$$f_i > 0, x_i(0) > 0 \ \forall i = 1, 2, \dots, n \implies x_i(t) > 0 \ \forall t \geq 0.$$

In other words, none of the variables is going to vanish and hence, the system is *permanent* in the sense that no member of a hypercycle dies out in the limit of long times, $\lim_{t \rightarrow \infty} x_i(t) \neq 0 \ \forall i = 1, \dots, n$. The existence of a Hamiltonian arc, that is, a closed loop of directed edges visiting all nodes once, is a sufficient condition for permanence (Hofbauer & Sigmund, 1998). It is also a necessary condition for low-dimensional systems with $n \leq 5$, but there exist permanent

Figure 1. Definition of hypercycles. Replicator equations as described by the differential equation (2) can be symbolized by directed graphs: the individual species are denoted by nodes and two nodes are connected by an edge, $j \rightarrow i$, if and only if $a_{ij} > 0$. The graphs of hypercycles consist of single Hamiltonian arcs as sketched on the left-hand side of the figure. These dynamical systems are permanent independent of the choice of rate parameters f_i . For $n \leq 5$ they represent the only permanent systems, but for $n \geq 6$ the existence of a single Hamiltonian arc is only a sufficient but not a necessary condition for permanence. The graph on the right-hand side, for example, does not contain a Hamiltonian arc but the corresponding replicator equation is permanent for certain choices of rate parameters (Hofbauer & Sigmund, 1998).

Figure 2. Solution curves of small elementary hypercycles. The figure shows the solution curves of Equation (1) with $f_1 = f_2 = \dots = f_n = 1$ for $n=2$ (upper left picture), $n=3$ (upper right picture), $n=4$ (lower left picture), and $n=5$ (lower right picture). The initial conditions were $x_1(0) = 1 - (n-1) \cdot 0.025$ and $x_k(0) = 0.025 \forall k=2, 3, \dots, n$. The sequence of the curves $x_k(t)$ is $k=1$ full black line, $k=2$ full gray line, $k=3$ hatched black line, $k=4$ hatched grey line, and $k=5$ black line with long hatches. The cases $n=2, 3$, and 4 have stable equilibrium points in the middle of the concentration space $c = (1/n, 1/n, \dots, 1/n)$; Equation (1) with equal rate parameters, $n=4$, and linearized around the midpoint c exhibits a marginally stable “center” and very slow convergence is caused by the nonlinear term, which becomes smaller as the system approaches c . For $n=5$, the midpoint c is unstable and the trajectory converges toward a limit cycle (Hofbauer et al., 1991).

dynamical systems for $n \geq 6$ without a Hamiltonian arc; one example is shown in Figure 1.

The dynamics of Equation (1) remains qualitatively unchanged when all rate parameters are set equal: $f_1 = f_2 = \dots = f_n = f$, which is tantamount to a *barycentric* transformation of the differential equation (Hofbauer, 1981). The hypercycle is invariant with respect to a rotational change of variables, $x_i \Rightarrow x_{i+1}$ with $i=1, 2, \dots, n; i \bmod n$, it has one equilibrium point in the center, and its dynamics depends exclusively on n . Some examples with small n are shown in Figure 2. The systems with $n \leq 4$ converge toward stable equilibrium points, whereas the trajectories of Equation (1) with $n \geq 5$ approach limit cycles. Independent of n , elementary hypercycles do not sustain chaotic dynamics.

Hypercycles have two inherent instabilities, which are easily illustrated for molecular species: (i) The members of the cycle may also catalyze the formation of nonmembers that do not contribute to the growth of the hypercycle, and thus hypercycles are vulnerable to parasitic exploitation (Eigen & Schuster, 1978a,b), and (ii) concentrations of individual species in oscillating hypercycles ($n \geq 5$) go through very small values, and these species might become extinct

through random fluctuations. More elaborate kinetic mechanisms can stabilize the system in Case (ii). Exploitation by parasites, Case (i), can be avoided by compartmentalization. Competition between different hypercycles is characterized by a strong nonlinearity in selection (Hofbauer, 2002): once a hypercycle has been formed and established, it is very hard to replace it by another hypercycle. Epochs with hypercyclic dynamics provide explanations for “once for ever” decisions or “frozen accidents.”

CATASTROPHE THEORY

Many natural phenomena (cell division, the bursting of bubbles, the collapse of buildings, and so on) involve discontinuous changes, whereas the majority of applied mathematics is directed toward modeling continuous processes. On the other hand, catastrophe theory is primarily concerned directly with singular behavior and as such deals with properties of discontinuities directly. This approach has found use in many and diverse fields and at one time was heralded as a new direction in mathematics, uniting singularity and bifurcation theories and their applications (Zeeman, 1976).

A simple mechanical system that illustrates the important ideas of discontinuous changes and hysteresis is provided by Zeeman's catastrophe machine (Zeeman, 1972, Poston & Stewart, 1996). A sketch showing its construction is given in Figure 1(a). It is recommended that readers make such devices for themselves and experiment with them.

The lines between Q, P, and the pointer represent rubber bands attached to a disk that rotates around O. Movement of the pointer such that it remains outside of the region ABCD results in a smooth motion of the wheel from one equilibrium state to another. This is illustrated by the path ℓ_1 in Figure 1(b), where x and θ are as defined in Figure 1(a) and k is a measure of the stiffness of the bands. However, starting with the pointer below AB and moving the pointer horizontally to cross AD will cause an anticlockwise jump in the wheel. This is equivalent to following the path ℓ_2 in Figure 1(b). This equilibrium will remain until AB is crossed when the pointer is moved backwards. The loci DAB form a cusp in the parameter space of the system where AD and AB are lines of folds that meet at the cusp point A. The cusp is a projection down onto the plane of a three-dimensional folded surface. The region labeled ABCD comprises four such cusps, each of which can be described by a simple cubic equation. Indeed, the set can be obtained from an approximate model for the machine (Poston & Stewart, 1996).

The term *catastrophe* was introduced by René Thom in 1972 to describe such discontinuous changes in a system where a parameter is changed smoothly.

Figure 1. (a) Sketch of Zeeman's catastrophe machine, (b) A sketch of the three-dimensional solution surface and its projection onto two dimensions near the cusp A.

Zeeman (1976) then coined the phrase *catastrophe theory*, and an explosion of applications arose ranging from the physical to the social sciences. An important idea put forward is that there are seven elementary catastrophes that classify most types of observed discontinuous behavior. They are the fold, cusp, swallowtail, and butterfly catastrophes and the elliptic, hyperbolic, and parabolic umbilic catastrophes. These describe all possible discontinuities for potential systems that are controlled by up to four variables. They are ordered according to their typicality of occurrence with the fold being the most common. A path of folds will be represented by a line of singular behavior in parameter space and a cusp will be formed when two such lines meet. Indeed, these two singularities are sufficient to cover most of the observed macroscopic critical behavior in practical applications.

One area of application where catastrophe theory has been used with considerable success is in optical caustics (Nye, 1999). Common experience of this phenomenon is observation of a distant light source through a drop of water on a window pane where a web of bright lines separated by dark regions can often be seen. The bright lines on the bottom of swimming pools are also examples of caustics where the bright sunlight is focused by the surface of the water. In this case, the line caustics are examples of paths of folds in the ray surfaces. An example of an optical cusp is provided by strong sunlight focused on the surface of a cup of coffee where two principal fold lines are made to meet by the curvature of the cup. In an outstanding series of experiments (Berry, 1976), a laser beam was shone through a water drop and a whole sequence of catastrophes was uncovered including swallowtails. All of the observed patterns can be reproduced in detail using the equations of ray optics (Nye, 1999).

Catastrophe theory has also been used to explore in some detail the state selection process in Taylor–Couette flow between concentric cylinders. In this case, even numbers of vortices are generated in the flow field, and the number that is realized depends

on the length of the cylinders. For a given length of the cylinder, one state develops smoothly, with control parameter and neighboring states delimited by fold lines in parameter space. The fold lines meet in a cusp that has been observed experimentally (Benjamin, 1978) and calculated numerically (Cliffe, 1988) from the Navier-Stokes equations.

There has been considerable criticism of catastrophe theory on both technical and practical grounds (Arnol'd, 1986; Arnol'd et al., 1994). For example, it is known that critical behavior or bifurcations in some multidimensional gradient systems do not reduce to critical points of potentials (Guckenheimer, 1973). Also, the ideas have been applied to a wide range of social, financial, and biological applications where the governing rules are not known or are very primitive. Very often, it is a case of re-interpretation of common experience in terms of technical mathematical language, which is most often qualitative rather than quantitative (Arnol'd, 1986). Hence, it is often the case that disparate systems superficially appear the same, but closer examination reveals that they are quite different in terms of important details.

CAUSALITY

Basic to science as well to common sense is the root notion of causality, that things and processes in the world we experience are not totally random, but ordered in specific ways that allow for rational understanding through explanations of various types. In the transition from a mythological worldview to a rational one, the notion of guilt (in Greek *aitia*), as in a criminal being guilty of a crime, was metaphorically used to describe nonpersonal natural processes whenever one phenomenon would necessarily follow another. As one aim of modern science is to uncover the deep structure of the world beyond our immediate experience, its explanations deal with the different determinants (or causes) of processual order. Three classical conceptions of inquiry, associated with the traditions of Plato, Aristotle, and Archimedes, have provided influential ideas about the role of causal explanations in science.

In the Platonic tradition, certain properties of nature could be derived from a priori given mathematical structures. As discovered by the Pythagorean philosophers of nature, a specific mathematical structure (relations between small whole numbers) could be the key to a part of nature (such as acoustics), so why not see whether that same structure could also describe other areas (such as astronomy)? Although the latter attempt failed, the general idea of using the power of demonstrative or formal necessity in mathematics as a descriptive tool of natural causality is still vital in many areas of science, including cosmology and high-energy physics. Also, the use of analog mathematical structures to describe phenomena has become standard.

The Aristotelian tradition did not refuse mathematical description but saw it only as a tool in a search for the real causes of things. For Aristotle, there were four kinds of causes: the material cause (*hyle* or *causa materialis*) that describes the stuff of which something is made, the formal cause (*eidos* or *causa formalis*) that describes the organization of something, the efficient cause (*to kineti'kon* or *causa efficiens*) that describes the active forces by which the phenomenon comes into being, and the final cause (*to telos* or *causa finalis*) that describes the purpose that it serves. Thus, for a house, bricks and mortar are its material cause, the plan of the house is its formal cause, the mason building it is its efficient cause, and the purpose of sheltering a family is its final cause.

In that ancient world of Aristotle, each phenomenon generally served a purpose. Aristotle did not consider the four causes as necessarily separate aspects of nature, but more like principles of explanation that may sometimes merge, as in the sprouting acorn becoming an oak tree where the formal, efficient, and final causes work together to actualize the characteristics of an adult oak. The popular renaissance critique of the final cause as implying the paradox of a future state (a goal)

influencing a present state led to a dismissal of any pluralist conception of causes. In the subsequent mechanical world picture, only efficient causes were left as explanatory. The life sciences could not live up to this reduction but continued as a descriptive natural history with an essentially Aristotelian outlook, at least until Darwin would explain the final cause of adaptations by the efficient causes of natural selection and heredity. Yet, even the Darwinian paradigm could not account for the nonlinear mechanisms of self-organization in the organism's embryonic development. Such goal-like (teleological) properties of development and self-reproduction remained necessary yet unexplained preconditions for the mechanics of natural selection.

The Archimedean tradition was founded by disciplines more physical than mathematical, although combining the two, such as optics, astronomy, mechanics, and music theory. The mathematical relations discovered by Archimedes (ca. 287–212 BC) in his books on mechanics were not *a priori*, as in the Platonic tradition, but derived from experience. However, the Aristotelian pursuit after the causes of the phenomena, especially the final ones, was regarded as metaphysical and so ignored. The Archimedean tradition includes such names as Ptolemaios, Johannes Kepler, Galileo Galilei, and Isaac Newton. Kepler started out as a Platonic, aiming to explain the Copernican system (which placed the Sun at the center of the solar system, in opposition to the Ptolemaic system) by regular polyhedrons, but failed and found the right laws for planetary movements through a mathematical analysis of Tycho Brahe's empirical observations. Galileo found his laws of falling bodies by eschewing the search for a hypothetical cause of gravitational force and instead using measures proportional to the velocity of a moving body for the effect of this force.

Although the mechanical worldview emphasizes only the role of efficient causes as principles of explanation in physics, the very idea of cause gave way for a long period to skepticism about proving any real existence of causes (the positivism of David Hume), eventually seeing the concept of cause as a feature of the observing subject (the transcendental idealism of Immanuel Kant). Yet, in physics, the laws of nature as expressed in terms of mathematics came to play the explanatory role of the causes of a system's movement. It was assumed that any natural system could be encoded into some formalism (e.g., a set of differential equations representing the basic laws governing the system) and that the entailment structure of that formalism perfectly mirrored the (efficient) causal structure of that part of nature. This view was compatible with a micro-determinism where a system's macroscopic properties and processes are seen as completely determined by the behavior of the system's constituent particles, governed by deterministic laws.

This view was deeply questioned by quantum physics, and by Rosen's work on fundamental limits on dynamic models of causal systems.

The complexity of causality, especially in goal-directed systems, was presaged by cybernetic research in the 1940s, dealing with negative feedback control (in animals and artifacts such as self-guiding missiles) and the role of information processing for the regulation of dynamic systems. A paradigmatic example is the closed causal loops connecting various physiological levels of hormones in the body, essential for maintaining a constant internal environment (homeostasis)—a modern version of the ancient symbol of uroboros, the snake biting its own tail.

The emergence of nonlinear science in the late 20th century increased interest in the old idea that causal explanations may not all reduce to simple one-to-one correspondences between cause and effect. The realization that complex systems may occupy different areas in phase space characterized by qualitatively distinct attractors, eventually separated by fractal borders, has questioned micro-determinism even more than the fact that many such nonlinear systems have a high sensitivity to the initial conditions (the butterfly effect).

Another insight is that complex things often self-organize as high-level patterns via processes of local interactions between simple entities. This emergence of wholes (or collective behavior of units) may be mimicked in causal explanations. Instead of top-down reductive explanations, nonlinear science provides additional bottom-up explanations of emergent phenomena. Although these explanations are still reductive (in the methodological sense that one can show exactly what is going on from step to step in a simulation of the system), the complexity makes prediction impossible; thus, computational shortcuts to predict a future state can rarely be found.

As an emergent whole is formed bottom-up, its organization constrains its components in a top-down manner, that has been called downward causation (DC). There are three interpretations of DC: in strong DC, the emergent whole (a human mind) effectuates a change in the very laws that govern the lower-level (like free will might suspend what normally determines the action of the brain's neurons). This interpretation is often related to vitalist and dualist conceptions of life and mind and is hard to reconcile with science. In medium DC, lower-level laws remain unaffected; yet, their boundary conditions are constrained by the emergent pattern (a mental representation), which is considered just as real as the components of the system (neuronal signaling). Here, the state of the higher level works as a factor selecting which of the many possible next states of the high level may emerge from the low level. In weak DC, the emergent higher levels are seen as regulated by stable (cyclic or chaotic) attractors for the dynamics of the lower level. The fact that a biological species consists of

stable organisms is not solely a product of natural selection, but is a result of such internal, formal properties in the system's organization—the job of natural selection being to sort out the possible stable organisms and find those most fit for the given milieu (Kauffman, 1993; Goodwin, 1994). It should be emphasized that DC is not a form of efficient causation (involving a temporal sequence from cause to effect), rather it is a modern version of the Aristotelian formal and final cause.

Nonlinear science may be said to integrate a Platonic appreciation of universality (as found in the equations governing the passage to chaos in systems of quite distinct material nature), an Aristotelian acceptance of several types of causes, and an Archimedean pragmatism regarding the deeper status of determinism and causality. The latter is reflected in the fact that although deterministic chaos characterizes a large class of systems, this does not imply that these systems (or nature) are fully deterministic. The determinism refers to the mathematical tools used rather than an ontological notion of causality.

CELESTIAL MECHANICS

Although its origins can be traced back in antiquity to the first attempts of explaining the apparently irregular wandering of the planets, celestial mechanics was born in 1687 with the release of Isaac Newton's *Principia*. In 1799, Pierre-Simon Laplace introduced the term *mécanique céleste* (Laplace, 1799), which was adopted to describe the branch of astronomy that studies the motion of celestial bodies under the influence of gravity. Celestial mechanics is researched and developed by astronomers and mathematicians; the methods used to investigate it including numerical analysis, the theory of dynamical systems, perturbation theory, the quantitative and qualitative theory of differential equations, topology, the theory of probabilities, differential and algebraic geometry, and combinatorics.

Ptolemy's idea of the epicycles—according to which planets are orbiting on small circles, whose centers move on larger circles, whose centers move on even larger circles around the Earth—dominated astronomy in antiquity and the Middle Ages. In 1543, after working for more than 30 years on a new theory, Copernicus finished writing *De Revolutionibus*, a book in which he expressed the motion of the planets with respect to a heliocentric reference system, that is, one with the Sun at its origin. This allowed Kepler to use existing observations and formulate three laws of planetary motion, published in 1609 in *Astronomia Nova*:

- (i) *The law of motion*: every planet moves on an ellipse having the sun at one of its foci.
- (ii) *The law of areas*: every planet moves such that the segment planet-sun sweeps equal areas in equal intervals of time.
- (iii) *The harmonic law*: the squares of the periods of any two planets are to each other as the cubes of their mean distances from the sun.

But all these achievements were empirical, based on observations, not on deductions obtained from a more general physical law.

In 1666, Newton came up with the idea that the attractive force responsible for the free fall of objects might be the same as the one keeping the Moon in its orbit. He conjectured that the expression of this force is directly proportional to the product of the masses and inversely proportional to the square of the distance between bodies. The tools of calculus, which he had invented independent of—and at about the same time as—Gottfried Wilhelm von Leibniz, allowed him to proceed with the computations. Two decades later, in *Principia*, Newton proved the correctness of his theory. Kepler's laws follow as consequences. They are obtained from the differential equations of the Newtonian two-body problem (also called the Kepler problem) given by a potential energy of the form $U(r) = -Gm_1m_2/r$, where G is the gravitational

constant and r is the distance between the bodies of masses m_1 and m_2 .

After Newton, mathematicians, such as Johann Bernoulli, Alexis Clairaut, Leonhard Euler, such as Jean d'Alembert, Laplace, Joseph-Louis Lagrange, Siméon Poisson, Carl Jacobi, Karl Weierstrass, and Spiru Haretu, attacked various theoretical questions of celestial mechanics (e.g., the 2- and 3-body problem, the lunar problem, the motion of Jupiter's satellites, and the stability of the solar system) mostly with the quantitative tools of analysis, algebra, and the theory of differential equations. On the practical side, the first resounding success in the field was the prediction of the return of Halley's comet, which occurred in 1758—as the calculations had shown. An even more spectacular achievement came in 1846 with the discovery of the planet Neptune on the basis of the perturbation theory through computations independently performed by John Couch Adams and Urbain Jean-Joseph Le Verrier. Having its origin in one of Euler's papers, which applied the calculus of trigonometric functions to the 3-body problem, perturbation theory is now an independent branch of mathematics (see, e.g., Verhulst, 1990; Guckenheimer & Holmes, 1983) that is often used in celestial mechanics.

An important theoretical advance was achieved by Henri Poincaré toward the end of the 19th century, when the questions of celestial mechanics—especially those concerning the Newtonian 3-body problem—received substantial attention. While working on this problem, Poincaré understood that the quantitative methods of obtaining explicit solutions for differential equations are not strong enough to help him make significant progress; thus, he tried to describe the qualitative behavior of orbits (e.g., stability, the motion in the neighborhood of collisions and at infinity, existence of periodic solutions) even when their expressions were too complicated or impossible to derive, which is the case in general. His ideas led to the birth of several branches of mathematics, including the theory of dynamical systems, nonlinear analysis, chaos, stability, and algebraic topology (Barrow-Green, 1997; Diacu & Holmes, 1996).

Today's astronomers working in celestial mechanics are primarily interested in questions directly related to the solar system, such as the accurate prediction of eclipses, orbits of comets and asteroids, the motion of Jovian moons, Saturn's rings, and artificial satellites. The invention of the electronic computer had a significant impact on the practical aspects of the field. The development of numerical methods allowed researchers to obtain good approximations of the planet's motion for long intervals of time. These types of results are also used in astronautics. No space mission, from the Sputnik, Apollo, and Pioneer programs to the space shuttle, the Hubble telescope launch, and the recent international space

collaboration projects, could have been possible without the contributions of celestial mechanics.

Contemporary mathematicians active in the field are mostly dealing with theoretical issues, as, for example, the study of the general N -body problem and its particular cases (Wintner, 1947) ($N = 2, 3, 4$, the collinear, isosceles, rhomboidal, Sitnikov, and planetary problems, central configurations, etc.), attempting to answer questions regarding motion near singularities and at infinity, periodic orbits, stability and chaos, oscillatory behavior, Arnol'd diffusion, etc. Some researchers also study alternative gravitational forces like that suggested by Manev (Diacu et al., 2000; Hagihara, 1975; Moulton, 1970), which offers a good relativistic approximation at the level of the solar system.

Celestial mechanics and mathematics have always influenced each other's development, a trend that is far from slowing down today. The contemporary needs of space science bring a new wave of interest in the theoretical and practical aspects of celestial mechanics, making its connections with mathematics stronger than ever before.

CELL ASSEMBLIES

The term *cell assembly* became well established as a neuropsychological concept with the publication in 1949 of Donald Hebb's book *The Organization of Behavior*. A cell assembly forms when a group of cortical neurons gets wired together through experience-dependent synaptic potentiation induced by nearly synchronous activity in pairs of connected neurons. Once formed, it serves as a cooperative and

holistic mental representation. The mutual excitation within the active cell assembly influences network dynamics such that (i) the entire group of cells can be activated by stimulating only a part of it and (ii) once active, the ensemble displays afteractivity outlasting the stimulus triggering it. An important extension of the concept was suggested by Peter Milner, who proposed that negative feedback from lateral inhibition is essential to prevent mass activation of the entire network and the emergence of epileptic-like activity (Milner, 1957). This also introduces an element of competitive interaction between the cell assemblies allowing one assembly at a time to dominate the network. Hebb further proposed that cell assemblies activated in succession would wire together to form "phase sequences" that might be the physiological substrate of chains of association and the flow of thought. The concept of cell assemblies has been extensively elaborated in the context of cortical associative memory (see, e.g., Fuster, 1995).

Notably, abstract attractor network models (Hopfield, 1982; Rolls and Treves, 1997) may be regarded as mathematical instantiations of Hebb's cell assembly theory. They have been useful, for example, to estimate how many assemblies can be stored in a network of a given size, the existence of spurious attractors, and the effect of sparse activity and diluted network connectivity.

The extensive recurrent neuronal circuitry required for the formation of cell assemblies is abundant in the cerebral cortex in the form of horizontal intracortical and cortico-cortical connections. The latter are myelinated and support fast communication over large distances. The existence of experience-dependent synaptic changes in the form of "Hebbian" long-term synaptic potentiation is very well experimentally established today. In light of what we now know about brain circuitry and neuronal response properties, it is reasonable to assume that a cell assembly may extend across large areas of sensory, motor, and association cortices, perhaps even involving subcortical structures like the thalamus and basal ganglia. Rather than individual neurons, the actual nodes of the cell assembly are likely to be cortical modules, that is, minicolumns, comprising a couple of hundred neurons and with a diameter of about 30 μm (Mountcastle, 1998). Feature detectors in primary sensory areas like the visual orientation columns described by David Hubel and Torsten Wiesel are typical examples. Although the modular organization of higher-order cortical areas is less obvious, it has been proposed that the cortical sheet actually comprises a mosaic of such minicolumns. A single-cell assembly would then engage a small fraction of them distributed over a large part of the brain.

The reverberatory afteractivity in an active cell assembly was proposed by Hebb (1949) to correspond to "a single content in perception" and last some

hundred milliseconds to half a second. Notably, this is of the same order as the duration of visual fixations and the period of cognitively relevant neurodynamical phenomena evident in EEG (e.g., the theta rhythm) and evoked potentials (Pulvermueller et al., 1994). Persistent activity over seconds but otherwise of the same origin has recently been proposed as a mechanism underlying working memory (Compte et al., 2000).

The cell assembly theory connects the cellular and synaptic levels of the brain with psychological phenomenology. It suggests explanations for the close interaction between memory and perception, including the holistic and reconstructive nature of Gestalt perception, perceptual fusion of polymodal stimuli, and perceptual illusions. Typical examples are perceptual completion and filling in as when looking at the Kaniza triangle and perceptual rivalry as demonstrated by the slowly alternating perception of an ambiguous three-dimensional stimulus like the Necker cube (Figure 1). An analogy to Gestalt perception in the motor domain would be motor synergies, and their existence can also be understood based on the cell assembly theory. In the motor control domain, however, the

Figure 1. Two perceptual illusions that may be understood in terms of cell assembly dynamics.

temporal component of the underlying neurodynamics is critical, and for instance, finely tuned temporal sensory-motor coordination cannot be explained within this paradigm alone.

The neurodynamics of cell assemblies has been studied in a network with biophysically detailed model neurons (see, e.g., Lansner and Frasnén, 1992; Frasnén and Lansner, 1998), showing that the cellular properties of cortical pyramidal cells promote sustained activity. Moreover, the experimentally observed level of mutual excitation is sufficient to support such activity, and the measured magnitude of cortical lateral inhibition is effective in preventing coactivation of assemblies. The time to activate an entire assembly from a part of it was found to be within 50–100 ms in accordance with psychological experimental results. Modeling has further shown that neuronal adaptation due to accumulation of slow afterhyperpolarization (presumably together with synaptic depression) is a likely cause of termination of activity in an active assembly. Afteractivity may typically last some 300 ms, but the network dynamics is quite sensitive to endogenous monoamines such as serotonin, which acts by modulating the neuronal conductances underlying such adaptation. Further, simulations demonstrate that a cell assembly can survive even if the average conduction delay between the participating neurons increases to 10 ms, corresponding to a spatial extent of about 50 mm at axonal conduction velocities of 5 m/s. Despite quite powerful mutual excitation, reasonably low firing rates of cortical cells can be obtained in models with saturating synapses with slow kinetics (e.g., NMDA receptor gated channels) together with cortical feedback inhibition.

Although biologically highly plausible and supported by computational models, solid experimental evidence for the existence of cell assemblies is still lacking. Detection of their transient and highly distributed and diluted activity requires simultaneous noninvasive measurement in awake animals of the activity in a large number of neurons with high spatial and temporal resolution. This is still beyond the reach of current experimental techniques. Nevertheless, Hebb's original proposal has remained a vital hypothesis for more than half a century and it continues to inspire much experimental and computational research aimed at understanding how the brain works.

CELLULAR AUTOMATA

Following a suggestion by Stanislaw Ulam, John von Neumann developed the concept of cellular automata (CA) in 1948. Von Neuman wanted to formalize a set of primitive logical operations that were sufficient to evolve the complex forms of organization necessary for life. In doing this, he constructed a two-dimensional self-replicating automaton and initiated not only the study of CA but also the idea, now popular among students of complexity theory, that highly complex global behavior can be generated from local interaction rules. Much of the interest in CA has been motivated by their ability to generate complex spatial and temporal patterns from simple rules. Because of this, they provide a rich modeling environment, having the twin virtues of mathematical tractability and representational robustness (see Burk, 1970, for discussion of much of the early work on CA).

The non-obvious connection between simple local rules of interaction and emergent complex global patterns offers a possible approach to an explanation of complexity through determination of its generating local interactions. Some researchers have gone so far as to suggest that the universe itself is a CA, or CA-like object, and that sets of local generative interaction rules can replace differential equations as the standard mathematical expression for physical models.

CA are spatially and temporally discrete symbolic dynamical systems defined in terms of a lattice of sites (or cells), an alphabet of symbols that can be assigned to lattice sites, and a local update rule that

determines what symbol is assigned to each site at time $t+1$ on the basis of the site values in a local neighborhood of that site at time t . Given the local neighborhood structure, a neighborhood state is defined by an assignment of symbols from the alphabet to each site in the neighborhood. The local update rule can be specified in terms of a look-up table that lists the set of neighborhood states together with the symbol that each one assigns to the designated site at the next time step.

For example, if the lattice is isomorphic to the integers, the alphabet is 0, 1, and the neighborhood of any site s is the set of sites $s-1, s, s+1$, then there are 256 possible update rules, defined by the look-up table:

000	001	010	011	100	101	110	111
x_0	x_1	x_2	x_3	x_4	x_5	x_6	x_7

(The updated symbol is entered in the central cell. This defines what are called nearest-neighbor rules.) Here, each of the x_i is either 0 or 1 depending on the specific rule. Thus, they can be thought of as components of the rule.

A cellular automaton can be defined in any number of dimensions. Von Neuman's original automaton was two dimensional, as is what is perhaps the best-known CA—Conway's Game of Life (Gardner, 1970). This is one of the simplest two-dimensional CA known to be equivalent to a universal Turing machine.

If Σ is the full state space for a CA, then the local update rule defines a global mapping $\psi: \Sigma \rightarrow \Sigma$. Much of the analytical work on CA has been directed at determining the mathematical properties of the map ψ . A fundamental paper published by Hedlund in 1969 showed that CA are just the shift-commuting endomorphisms of the shift dynamical system. It is also known that surjectivity (a function is surjective, or onto, if every state has at least one predecessor) of the map ψ is decidable only in dimension one and that for one-dimensional additive rules (i.e., those satisfying the condition $\psi(\mu + \mu') = \psi(\mu) + (\mu')$), injectivity is equivalent to a certain rule-dependent complex polynomial having no roots that are n th roots of unity for any n . (A function is injective, or one to one, if every state has at most one predecessor. A function that is both surjective and injective is called reversible.)

From the early 1960s until the early 1980s, much of the work on CA was either simple applications or mathematical analysis. The terminology was not settled, and work can be found under the names *cellular structures*, *cellular spaces*, *homogeneous structures*, *iterative arrays*, *tessellation structures*, and *tessellation arrays*.

As computers became powerful enough to support the intense calculations required, however, an experimental mathematics approach became possible. In addition, solution of systems of differential equations by computer makes use of numerical combination rules

on a discrete lattice, and CA are the simplest examples of such rules, adding impetus to interest in their study.

Concurrent with the appearance of powerful computers, work was initiated on the physics of computation, and the construction of reversible automata that, it was supposed, would be a discrete equivalent to the time-invariant differential equations of physics. More or less simultaneously, Stephen Wolfram began to publish a series of papers that popularized the study of elementary automata (see Wolfram, 1994), and by the mid-1980s, CA had emerged as a major field of interest among research in the field of complex systems theory.

Because of their generality as a modeling platform, CA have found wide application in many areas of science. In chemistry and physics, they have provided models of pattern formation in reaction-diffusion systems, the evolution of spiral galaxies, spin exchange systems and Ising models, fluid and chemical turbulence (especially as lattice gas automata), dendritic crystal growth, and solitons, among other applications.

Spatially recurring patterns that propagate in the space-time evolution of certain CA have been likened to particles moving in physical space-time. The interactions of these "particles" are important in attempts to use CA for computational tasks (e.g., Crutchfield & Mitchell, 1995). It has also been pointed out that these particles are analogous to the defects, or coherent structures found in pattern formation processes in condensed matter physics, and to solitons in hydrodynamics. The best-known examples of such particles are the so-called "gliders" that occur in Conway's game of life.

Numerous connections have also been shown between fractals and cellular automata. Rescaling the space-time output of a CA often generates a fractal, as, for example, the two-site rule defined by $00, 11 \rightarrow 0, 01, 10 \rightarrow 1$ generates the well-known Sierpinski gasket (Peitgen, Jürgen & Saupe, 1992).

In biology and medicine, CAs have been applied in models of heart fibrillation, developmental processes, evolution, propagation of diseases infectious, plant growth, and ecological simulations.

In computation, CAs have been used as parallel computers, sorters, prime number sieves, and tools for encryption and for image processing and pattern recognition. Some automata have the capacity for universal computation, although how to implement this capacity remains problematic.

Cellular automata have also been used to model social dynamics (Axtell & Epstein, 1996), the spread of forest fires, neural networks, and military combat situations. Extensive references to these applications and others can be found in Voorhees (1995) and Ilachinski (2001).

Work on CA has also stimulated work on other systems that generate complex patterns based on local rules. There are close connections to the fields of artificial life, random Boolean networks, genetic programming and evolutionary computation (Mitchell, 1996), and the general theory of computational mechanics.

A web search under the key word "cellular automata" will turn up literally hundreds of sites devoted to various aspects of their study. A particularly useful program for the study of CA, Boolean networks, and other discrete iterated systems is *Discrete Dynamics Lab* (Wuensche & Lesser, 1992), available for downloading from <http://www.ddlab.com>.

CELLULAR NONLINEAR NETWORKS

The development of cellular nonlinear networks (CNN) is embedded in the history of the electronic and computer industry, which is characterized by three revolutions: cheap computing power via microprocessors (since the 1970s), cheap bandwidth (since the end of the 1980s), and cheap sensors and MEMS (micro-electro-mechanical system) arrays (since the end of the 1990s). These research and technology breakthroughs led the way for several important economic enterprises such as the PC industry of the 1980s, the Internet indus-

try of the 1990s, and the future analog computing industry, which is growing, together with optical and nanoscale implementations on the atomic and molecular level. Analog cellular computers have been the technical response to the sensors revolution, mimicking the autonomy and physiology of sensory and processing organs.

The CNN was invented by Leon O. Chua and Lin Yang in Berkeley in 1988. The main idea behind the CNN paradigm is Chua's so-called "local activity principle," which asserts that no complex phenomena can arise in any homogeneous media without local activity. Obviously, local activity is a fundamental property in microelectronics, where, for example, vacuum tubes and, later on, transistors are locally active devices in the electronic circuits of radios, televisions, and computers. The demand for local activity in neural networks was motivated by practical technological reasons. In 1985, John Hopfield theoretically suggested a neural network, which, in principle, could overcome the failures of pattern recognition in Frank Rosenblatt's perceptron (See **Perceptron**). However, its globally connected architecture was highly impractical for technical realizations in VLSI (very-large-scale-integrated) circuits of microelectronics: the number of wires in a fully connected Hopfield network grows exponentially with the size of the array. A CNN only needs electrical interconnections in a prescribed sphere of influence.

In general, a CNN is a nonlinear analog circuit that processes signals in real time. It is a multicomponent system of regularly spaced identical ("cloned") units, called cells, which communicate with each other directly only through their nearest neighbors. However, the locality of direct connections also permits global information processing. Communications between nondirectly (remote) connected units are obtained on passing through other units. The idea that complex and global phenomena can emerge from local activities in a network dates back to John von Neumann's first paradigm of cellular automata (CA). In this sense, the CNN paradigm is a higher development of the CA paradigm under the new conditions of information processing and chip technology. Unlike conventional cellular automata, CNN host processors accept and generate analog signals in continuous time with real numbers as interaction values. Furthermore, the CNN paradigm allows deep insights into the dynamic complexity of computational processes. While the classification of complexity by CA was more or less inspired by empirical observations of pattern formation in computer experiments, the CNN approach delivers a mathematically precise measure of dynamic complexity. The basic idea is to understand cellular automata as a special case of CNNs that can be characterized by a precise code for attractors of nonlinear dynamical systems and by a unique complexity index.

Figure 1. Standard CNN with array (a), 3×3 and 5×5 neighborhood (b,c).

Mathematical Definition

A CNN is defined by (1) a spatially discrete set of continuous nonlinear dynamical systems (cells or neurons) where information is processed into each cell via three independent variables (input, threshold, initial state) and (2) a coupling law relating relevant variables of each cell to all neighboring cells within a prescribed sphere of influence. A standard CNN architecture consists of an $M \times N$ rectangular array of cells $C(i, j)$ with cartesian coordinates (i, j) with $i = 1, 2, \dots, M$ and $j = 1, 2, \dots, N$ (Figure 1a). Figures 1b–c show examples of cellular spheres of influence as 3×3 and 5×5 neighborhoods. The dynamics of a cell's state is defined by a nonlinear differential equation (CNN state equation) with scalars for state x_{ij} , output y_{ij} , input u_{ij} , and threshold z_{ij} , and coefficients, called "synaptic weights", modeling the intensity of synaptic connections of the cell $C(i, j)$ with the inputs (feedforward signals) and outputs (feedback signals) of the neighboring cells $C(k, l)$. The CNN output equation connects the states of a cell with the outputs.

The majority of CNN applications use space-invariant standard CNNs with a cellular neighborhood of 3×3 cells and no variation of synaptic weights and cellular thresholds in the cellular space. A 3×3 sphere of influence at each node of the grid contains nine cells with eight neighboring cells and the cell in its center. In this case, the contributions of the output (feedback) and input (feedforward) weights can be reduced to two fixed 3×3 matrices, which are called feedback (output) cloning template **A** and feedforward (input) cloning template **B**. Thus, each CNN is uniquely defined by the two cloning templates **A**, **B**, and a threshold z , which consist of $3 \times 3 + 3 \times 3 + 1 = 19$ real numbers. They can be ordered as a string of 19 scalars with a uniform threshold, nine feedforward, and nine feedback synaptic weights. This string is called a "CNN gene" because it completely determines the dynamics of the CNN. Consequently, the universe of all CNN genes is called the "CNN genome." In analogy to the human genome project, steady progress can be made by isolating and analyzing various classes of CNN genes and their influences on CNN genomes.

Applications

In visual computing, the triple **A**, **B**, z , and its 19 real numbers can be considered as a CNN macroinstruction on how to transform an input image into an output image. Simple examples are a subclass of CNNs with practical relevance such as the class $C(\mathbf{A}, \mathbf{B}, z)$ of space-invariant CNNs with excitatory and inhibitory synaptic weights, the zero-feedback (feedforward) class $C(\mathbf{0}, \mathbf{B}, z)$ of CNNs without cellular feedback, the zero-input (autonomous) class $C(\mathbf{A}, \mathbf{0}, z)$ of CNNs without cellular input, and the uncoupled class $C(\mathbf{A}^0, \mathbf{B}, z)$ of CNNs without cellular coupling. In $\mathbf{A}^0$, all weights are zero except for the weight of the cell in the center of the matrix. Their signal flow and system structure can be illustrated in diagrams that can easily be applied to electronic circuits as well as to typical living neurons.

CNN templates are extremely useful for standards in visual computing. Simple examples are CNNs detecting edges either in binary (black-and-white) input images or in gray-scale input images. An image consists of pixels corresponding to the cells of a CNN with binary or gray scale. Logic operators can also be realized by simple CNN templates in order to combine CNN templates for visual computing. The logic NOT CNN operation inverts intensities of all binary image pixels, the foreground pixels becoming the background, and vice versa. The logic AND (logic OR, respectively) CNN operation performs a pixel-wise logic AND (logic OR operation, respectively) on corresponding elements of two binary images. These operations can be used as elements of some Boolean logic algorithms that operate in parallel on data arranged in the form of images.

The simplest form of a CNN can be characterized via Boolean functions. We consider a space-invariant binary CNN belonging to the uncoupled class $C(\mathbf{A}^0, \mathbf{B}, z)$ with a 3×3 neighborhood that maps any static 3×3 input pattern into a static binary 3×3 output pattern. It can be uniquely defined by a Boolean function of nine binary input variables, where each variable denotes one of the nine pixels within the sphere of influence of a cell. Although there are infinitely many distinct templates of the class $C(\mathbf{A}^0, \mathbf{B}, z)$, there are only a finite number of distinct combinations of 3×3 pattern of black and white cells, namely, $2^9 = 512$. As each binary nine input pattern can map to either 0 (white) or 1 (black), there are 2^{512} distinct Boolean maps of nine binary variables. Thus, every binary standard CNN can be uniquely characterized by a CNN truth table, consisting of 512 rows with one for each distinct 3×3 black-and-white pattern, nine input columns with one for each binary input variable, and one output column with binary values of the output variable.

$2^{512} \approx 1.3408 \times 10^{154} > 10^{154}$ is an "immense" number (in the sense proposed by Walter Elsasser), although the uncoupled $C(\mathbf{A}^0, \mathbf{B}, z)$ CNNs are only

a small subclass of all CNNs. So, the question arises as to which subclass of Boolean functions exactly characterizes the uncoupled CNNs. In their critique of the perceptron (1969), M. Minsky and S. Papert introduced the concept of linearly separable and nonseparable Boolean functions. It can be proven that the class $C(A^0, \mathbf{B}, z)$ of all uncoupled CNNs with binary inputs and binary outputs is identical to the linearly separable class of Boolean functions. Thus, linearly nonseparable Boolean functions such as, for example, the XOR function cannot be realized by an uncoupled CNN. But the uncoupled CNNs can be used as elementary building blocks that are connected by CNNs of logical operations. It can be proved that every Boolean function of nine variables can be realized by using uncoupled CNNs with nine inputs and either one logic OR CNN, or one logic AND CNN, in addition to one logic NOT CNN.

Every uncoupled CNN $C(A^0, \mathbf{B}, z)$ with static binary inputs is completely stable in the sense that any solution converges to an equilibrium point. The waveform of the CNN state increases or decreases monotonically to the equilibrium point if the state at this point is positive or negative. Moreover, except for some degenerate cases, the steady-state output solution can be explicitly calculated by an algebraic formula without solving the associated nonlinear differential equations. Obviously, this is an important result to characterize a CNN class of nonlinear dynamics with robust CNN templates. Completely stable CNNs are the workhouses of the most current CNN applications. But there are also even simpler CNNs with oscillatory or chaotic behavior. Future applications will exploit the immense potentials of the unexplored terrains of oscillatory and chaotic operating regions. Then, Cellular Neural Networks will actually be transformed to Cellular Nonlinear Networks with all kinds of phase transitions and attractors of nonlinear dynamics.

Complexity Paradigm

From the perspective of nonlinear dynamics, it is convenient to think of standard CNN state equations as a set of ordinary differential equations with the components of the CNN gene as bifurcation parameters. Then, the dynamical behavior of standard CNNs can be studied in detail. Numerical examples deliver CNNs with limit cycles and chaotic attractors. The emergence of complex structures in nature can be explained by the nonlinear dynamics and attractors of complex systems. They result from the collective behavior of interacting elements in a complex system. The different paradigms of complexity research promise to explain pattern formation and pattern recognition in nature by specific mechanisms (e.g., Prigogine's chemical dissipation, Haken's work on lasers). From the CNN point of view, it is convenient to

study the subclass of autonomous CNNs where the cells have no inputs. In these systems, it can be explained how patterns can arise, evolve, and sometimes converge to an equilibrium by diffusion-reaction processes. Pattern formation starts with an initial uniform pattern in an unstable equilibrium that is perturbed by small, random displacements. Thus, in the initial state, the symmetry of the unstable equilibrium is disturbed, leading to rather complex patterns. Obviously, in these applications, cellular networks do not refer only to neural activities in nerve systems, but to pattern formation in general.

A CNN is defined by the state equations of isolated cells and the cell coupling laws. For simulating reaction-diffusion processes, the coupling law describes a discrete version of diffusion (with a discrete Laplacian operator). CNN state equations and CNN coupling laws can be combined in a CNN reaction-diffusion equation, determining the dynamics of autonomous CNNs. If we replace their discrete functions and operators by their limiting continuum version, then we obtain the well-known continuous partial differential equations of reaction-diffusion processes that have been studied in different complexity approaches. Chua's version of the CNN reaction-diffusion equation delivers computer simulations of these pattern formations in chemistry and biology (e.g., concentric, auto, and spiral waves). On the other hand, for any nonlinear partial differential equation, many appropriate CNN equations can be associated with it. In many cases, it is sufficient to study the computer simulations of associated CNN equations, in order to understand the nonlinear dynamics of these complex systems.

CNN Universal Machine and Programming

There are practical and theoretical reasons for introducing a CNN Universal Machine (CNN-UM). From an engineering point of view, it is totally impractical to implement different CNN components or templates with different hardwired CNNs. Historically, John von Neumann's general-purpose computer was inspired by Alan Turing's universal machine in order to overcome all the different hardware machines of the 1930s and 1940s for different applications. From a theoretical point of view, CNN-UM opens new avenues of analog neural computers. In the CNN-UM, analog (continuous) and logic operations are mixed and embedded in an array computer. It is a complex nonlinear system, which combines two different types of operations, namely continuous nonlinear array dynamics and continuous time with local and global logic. Obviously, the mixture of analog and digital components considerably resembles to neural information processing in living organisms. The stored program, as a sequence of templates, could

be considered as a genetic code for the CNN-UM. The elementary genes are the templates.

After the introduction of the architecture with standard CNN universal cells and the global analog programming unit (GAPU), the complete sequence of an analog CNN program can be executed on a CNN-UM. The description of such a program contains the global task, the flow diagram of the algorithm, the description of the algorithm in a high level α (analog) programming language, and the sequence of macro-instructions by a compiler in the form of an analog machine code (AMC). At the lowest level, the chips are embedded in their physical environment of circuits. The AMC code will be translated into hardware circuits and electrical signals. At the highest level, the α compiler generates a macro-level code called analog macro-code (AMC). The input of the α compiler is the description of the flow diagram of the algorithm using the language. In Figure 2, the levels of the software and the core engines are described. The analog macro code is used for software simulations running on a Pentium chip in a PC and for applications in a CNN-UM Chip with a CNN Chip Prototyping System (CCPS).

The CNN-UM is technically realized by analog and digital VLSI implementation. It is well known that any complex system of digital technology can be built from a few implemented building blocks by wiring and programming. In the same way, the CNN-UM, also containing analog building blocks, can be constructed. A core cell needs only three building blocks of a capacitor, resistor, and a VCCS (voltage-controlled current source). If a switch, a logic register, and a logic gate are added to the three building blocks, the extended CNN cell of the CNN-UM can be implemented. In principle, six building blocks plus wiring are sufficient to build the CNN-UM: resistor,

capacitor, switch, VCCS, logic register, logic gate. As in a digital computer, stored programmability can also be introduced for analog neural computers, enabling the fabrication of visual microprocessors. Similar to classical microprocessors, stored programmability needs a complex computational infrastructure with high-level language, compiler, macro-code, interpreter, operating system, and physical code, in order to make it understandable for the human user. Using this computational infrastructure, a visual microprocessor can be programmed by downloading the programs onto the chips, as in the case of classical digital microprocessors. Writing a program for an analog CNN algorithm is as easy as writing a BASIC program.

With respect to computing power, CNN computers offer an orders-of-magnitude speed advantage over conventional technology when the task is complex. There are also advantages in size, complexity, and power consumption. A complete CNN-UM on a chip consists of an array of 64×64 0.5 μm micron CMOS cell processors. Each cell is endowed not only with a sensor for direct optical input of images and video but also with communication and control circuitries, as well as local analog and logic memories. CNN cells are interfaced with their nearest neighbors, as well as with the outside world. A CNN chip with 4096 cell processors on a chip means more than 3.0 Tera-OPS (operations per second) equivalent of computing power, which is about a 1000 times faster than the computing power of an advanced Pentium processor. By exploiting the state-of-the-art vertical packaging technologies, close to 10^{15} OPS CNN-UM architectures can be constructed on chips with 200×200 arrays. Thus, CNN universal chips will realize Tera-OPS or even Penta- (10^{15}) OPS, which are required for high-speed target recognition and tracking, real-time visual inspection of manufacturing processes, and intelligent machine vision capable of recognizing context-sensitive and moving scenes.

CENTER MANIFOLD REDUCTION

A dynamical system might be difficult to solve, even numerically. To better understand its behavior in the neighborhood of an equilibrium, a reduction can be performed. For this, one starts with the eigenvalue spectrum λ of the linearized system. In the linear evolution $\sim \exp(\lambda t)$, eigenvalues with $\Re \lambda < 0$ ($\Re \lambda > 0$) are called stable (unstable), whereas those with $\Re \lambda = 0$ are called central.

In the neighborhood of an equilibrium point, P , of a dynamical system, in general, three different types of invariant manifolds exist: the trajectories belonging to the stable manifold M^s are being attracted by P , whereas those of the unstable manifold M^u are being repelled. The dynamics on the center manifold M^c depend on the nonlinearities. For the linearized problem, $E^s \equiv M^s$, $E^u \equiv M^u$, and $E^c \equiv M^c$ are uniquely determined linear subspaces that span the whole space. The transition to the nonlinear system causes (only) deformations of the linearly determined manifolds M_s , M_u , and M_c . However, the form of the latter critically depends on the nonlinear terms.

Let us elucidate that the behavior for the very simple system (Grosche et al., 1995)

$$\dot{x} = -xy, \quad \dot{y} = -y + x^2. \quad (1)$$

Here, the dot means differentiation with respect to time t . The equilibrium point P is $(0, 0)$, and the linearized system is

$$\dot{x} = 0, \quad \dot{y} = -y. \quad (2)$$

Here, we have the stable manifold E^s being identical to the y -axis and the center manifold E^c being identical to the x -axis. The linearized problem can be visualized by the graph shown in Figure 1.

Figure 1. The linear stable (E^s) and center manifold (E^c) for example (1).

Both manifolds will be deformed in the transition to the nonlinear system. The (nonlinear, perturbed) center manifold can be described in the present example by

$$M^c : y = h(x) \quad (3)$$

with $h(0) = h'(0) = 0$. Using that ansatz for the center manifold in (1), we obtain

$$\dot{x} = -x h(x). \quad (4)$$

Differentiating (3) with respect to t , leads to

$$\dot{y} = h'(x) \dot{x} \quad (5)$$

or

$$-h(x) + x^2 = h'(x)[-x h(x)], \quad (6)$$

that is, a differential equation for $h = h(x)$. Performing a power series ansatz $h(x) = cx^2 + dx^3 + \dots$, we find that $c = 1$. The (nonlinear) center manifold is thus given by

$$y = x^2 + \dots, \quad (7)$$

and the dynamics on it follows from

$$\dot{x} = -x^3; \quad (8)$$

that is, the trajectories are being attracted by P . For an illustration, see Figure 2.

More General Theoretical Background

Let us now generalize the idea and consider a system of ordinary differential equations (ODEs)

$$\dot{a} = Aa + N(a, b), \quad (9)$$

$$\dot{b} = Bb + M(a, b), \quad (10)$$

describing the dynamics of amplitudes $a_1, \dots, a_n$ and $b_1, \dots, b_m$ of n linear marginal stable modes and m linear stable modes, respectively $[(a_1, \dots, a_n) := a,$

Figure 2. The stable (M^s) and center manifold (M^c) for example (1).

$(b_1, \dots, b_m) := b$. This implies that the real parts of eigenvalues of the matrix A vanish, and the real parts of the eigenvalues of the matrix B are negative. The functions $N(a, b), M(a, b) \in C^r$ on the right-hand sides of Equations (9) and (10) represent the nonlinear terms. Let E^c be the n -dimensional (generalized) eigenspace of A and E^s be the m -dimensional (generalized) eigenspace of B . Under these assumptions, the center manifold theorem provides the following statement (Guckenheimer & Holmes, 1983):

There exists an invariant C^r manifold M^s and an invariant C^{r-1} manifold M^c that are tangent at $(a, b) = (0, 0)$ to the eigenspaces E^s and E^c , respectively. The stable manifold M^s is unique but the center manifold M^c is not necessarily unique.

Locally, the center manifold M^c can be represented as a graph,

$$M^c = \{(a, b) | b = h(a)\}, \quad h(0) = 0, \quad Dh(0) = 0, \quad (11)$$

where the C^{r-1} function h is defined in a neighborhood of the origin, and Dh denotes the Jacobi matrix. Introducing (11) in Equations (9) and (10), we obtain

$$\dot{a} = Aa + N(a, h(a)), \quad (12)$$

$$Dh(a) [Aa + N(a, h(a))] = Bh(a) + M(a, h(a)). \quad (13)$$

The solution h of Equation (13) can be approximated by a power series. The ambiguity of the center manifold is manifested by the fact that h is determined only modulo C^∞ , a non-analytic function; thus, the power series approximation of the function h is unique. The importance of the center manifold theory is reflected by the following theorem (Marsden & McCracken, 1976; Carr, 1981):

If there exists a neighborhood U^c of $(a, b) = (0, 0)$ on M^c , so that every trajectory starting in U^c never leaves it, then there exists a neighborhood U of

$(a, b) = (0, 0)$ in $\mathfrak{R}^n \times \mathfrak{R}^m$, so that every trajectory starting in U converges to a trajectory on the center manifold.

Therefore, it is sufficient to discuss the dynamics on the center manifold, described by Equation (12). If all solutions are bounded to some neighborhood of the origin, then we have described all features of the asymptotic behavior of Equations (9) and (10). In order to fulfill the condition, the function $N(a, h(a))$ has to be expanded up to a sufficiently high order. We end up with normal forms, for example, the third order may be adequate.

Very often, the problems contain parameters and, in addition, the systems may be infinite dimensional. In both cases, one can generalize the theory presented so far. Parameters can be taken into account by expanding Equations (9) and (10) to

$$\dot{a} = A(\Lambda)a + N(a, b, \Lambda), \quad (14)$$

$$\dot{b} = B(\Lambda)b + M(a, b, \Lambda), \quad (15)$$

$$\dot{\Lambda} = 0, \quad (16)$$

where $\Lambda = (a_{n+1}, \dots, a_{n+l})$ contains l parameters. The center manifold now has dimension $n + l$.

PDE Reduction and Symmetry Considerations

The theory is also valid in the infinite-dimensional case, if the spectrum of the linear operator can be split into two parts. The first part contains a finite number of eigenvalues whose real parts are zero, and the second part contains (an infinite number of) eigenvalues with negative real parts that are bounded away from zero.

To elucidate the power of center manifold reduction, let us consider the partial differential equation (PDE)

$$\frac{\partial \phi}{\partial t} + \phi \frac{\partial \phi}{\partial y} + \alpha \frac{\partial^2 \phi}{\partial y^2} + \beta \frac{\partial^3 \phi}{\partial y^3} + \frac{\partial^4 \phi}{\partial y^4} + v\phi = 0. \quad (17)$$

All coefficients α, β , and v are nonnegative. In the following, we treat β as a fixed parameter, and consider the dynamics in dependence in α and v . The linearization with $\phi \equiv 0$ as the equilibrium solution leads to

$$\omega = -\beta k^3 + i(-k^4 + \alpha k^2 - v) \quad (18)$$

when we assume a unit cell of length 2π with periodic boundary conditions. A typical dependence of the linear growth (or damping) rate $\gamma := \Im \omega$ is shown in Figure 3 for $\alpha = 5.25$ and $v = 3.8$.

The case of two unstable modes ($k = 1, 2$) is already highly nontrivial. Let us choose $\alpha = \alpha_c = 5$ and $v = v_c = 4$. Then, the modes $\phi^{(1)} = \sin y$, $\phi^{(2)} = \cos y$, $\phi^{(3)} = \sin 2y$, and $\phi^{(4)} = \cos 2y$ belonging to $k = 1$ and 2 , respectively, are marginally stable. We introduce

Figure 3. Growth rate curve, with two unstable modes at $k = 1$ and $k = 2$ for the PDE (17).

the four (real) amplitudes a_1, a_2, a_3 , and a_4 , as well as $\alpha_5 = \alpha - \alpha_c$ and $\alpha_6 = \nu - \nu_c$. The center manifold theory will allow us to derive a closed set of nonlinear amplitude equations

$$\dot{a}_n = f_n(a_1, \dots, a_6), \quad n = 1, \dots, 6, \quad (19)$$

which are valid in the neighborhood of the critical point α_c, ν_c . One has $f_5 = f_6 = 0$. The other functions f_n are written as a power series in a_n ,

$$f_n = \sum_{1 \leq m \leq 6} A_n^m a_m + \sum_{1 \leq m \leq p \leq 6} A_n^{mp} a_m a_p + \dots \quad (20)$$

The dynamics on the center manifold is characterized by $a_1, \dots, a_6$. Thus, we can make the ansatz (Carr, 1981)

$$\phi(y, t) = \sum_{1 \leq n \leq 4} a_n(t) \phi^{(n)}(y) + \sum_{1 \leq n \leq m \leq 6} a_n(t) a_m(t) \phi^{(nm)}(y), \quad (21)$$

where the $\binom{7}{2} = 21$ new functions $\phi^{(nm)}$ and, of course, the next $\binom{8}{3} = 56$ functions $\phi^{(nmp)}$, and so on, can be chosen orthogonal to $\phi^{(n)}$, $n = 1, \dots, 4$.

The technical procedure is now as follows. One inserts ansatz (21) into the basic equation (17) and compares equal orders in the amplitudes. For example, in the second-order, one collects equal powers $a_r a_s$; the “coefficients” (being equated to zero) will determine the unknown functions $\phi^{(nm)}$ via ODEs. Taking into account the (periodic) boundary conditions, we have to satisfy the solvability conditions. Collecting equal powers of the amplitudes a_n , we find the solutions for the coefficients A_r^{np} . With these values, we can solve for $\phi^{(mn)}$. This procedure should be continued to higher orders.

Actually, when written explicitly, one faces considerable work (in second order, we have to solve for 84, and in third order for 224 coefficients A_r^{np} , and so on). One can simplify the calculations by making use of symmetries.

Translational invariance implies the following. If $\phi(y)$ is a solution,

$$T_{y_0} \phi(y) := \phi(y + y_0) \quad (22)$$

will also satisfy the dynamical equation (17), where y_0 is a real shift parameter. (In the case $\beta = 0$, we also have the mirror symmetry $\phi(y) = \phi(-y)$.)

Remember the structure of the center manifold reduction: the modes $\phi^{(nm)}$, $\phi^{(nmp)}$, $\dots$ have to be determined from inhomogeneous differential equations. The inhomogeneities contain (in nonlinear forms) the marginal modes $\phi^{(r)}$, $r = 1, \dots, 4$. Thus, the so-called slaved modes can be written in symbolic form as

$$\phi^{(m\dots)} = h^{(m\dots)}[\{\phi^{(r)}\}]. \quad (23)$$

Thus, the following symmetry should hold:

$$T_{y_0} h^{(m\dots)}[\{\phi^{(r)}\}] = h^{(m\dots)}[T_{y_0} \{\phi^{(r)}\}]. \quad (24)$$

The consequences of the translational symmetry are most easily seen when combining the marginal modes to

$$\varphi := \sum_{r=1}^4 a_r \phi^{(r)} \equiv \Im(c_1 e^{iy} + c_2 e^{2iy}) \quad (25)$$

with the complex amplitudes $c_1 := a_1 + ia_2$, $c_2 := a_3 + ia_4$. The (complex) amplitude equations are

$$\dot{c} = g_n(c_1, c_2, a_5, a_6), \quad n = 1, 2, \quad (26)$$

$$\dot{a}_m = 0, \quad m = 5, 6. \quad (27)$$

The translational symmetry (22) requires

$$e^{iy_0} g_n(c_1, c_2, a_5, a_6) = g_n(e^{iy_0} c_1, e^{iy_0} c_2, a_5, a_6) \quad (28)$$

for $n = 1, 2$. The vector field (g_1, g_2) is called equivariant with respect to the operation

$$(c_1, c_2) \rightarrow (e^{iy_0} c_1, e^{iy_0} c_2). \quad (29)$$

The most general form of vector fields being equivariant under operation (28) is

$$(g_1, g_2) = (c_1 P_1 + \bar{c}_1 Q_2, c_2 P_2 + c_1^2 Q_2), \quad (30)$$

where P_1, P_2, Q_1 , and Q_2 are polynomials in $|c_1|^2, |c_2|^2$, and $\Re(c_1^2 \bar{c}_2)$; of course, they can also depend on a_5 and a_6 .

Keeping in mind the symmetry properties, the general form of the amplitude equations reduces to

$$\dot{c}_1 = \lambda c_1 + \mathcal{A} \bar{c}_1 c_2 + \mathcal{C} c_1 |c_1|^2 + \mathcal{E} c_1 |c_2|^2 + \mathcal{O}(|c|^4), \quad (31)$$

$$\dot{c}_2 = \mu c_2 + \mathcal{B} c_1^2 + \mathcal{D} c_2 |c_1|^2 + \mathcal{F} c_2 |c_2|^2 + \mathcal{O}(|c|^4), \quad (32)$$

$$\dot{a}_5 = \dot{a}_6 = 0. \quad (33)$$

A straightforward analysis leads to

$$\begin{aligned}\lambda &= a_5 - a_6 - i\beta, & \mu &= 4a_5 - a_6 + i8\beta, \\ \mathcal{A} &= \frac{1}{2}, & \mathcal{B} &= -\frac{1}{2}, \\ \mathcal{C} &= 0, & \mathcal{D} &= -\frac{3}{4(20-19\beta)}, \\ \mathcal{E} &= \frac{1}{2}D, & \mathcal{F} &= -\frac{1}{12(15-14\beta)}.\end{aligned}\quad (34)$$

This completes the center manifold reduction.

Very interesting conclusions result, for example, with respect to the number of modes and their interplay in time, from the systematic treatment with the center manifold theory. For example, one interesting aspect is that the present codimension-two analysis can describe successive bifurcations of one unstable mode, which, in some cases can lead to chaos in time.

CENTRAL LIMIT THEOREM

See Martingales

CHAOS VS. TURBULENCE

The notion of chaos has its genesis in the work of Henri Poincaré (See **Poincaré theorems**) on the three-body problem of celestial mechanics. Poincaré realized that this problem cannot be reduced to quadratures and solved in the manner of the two-body problem. A precise definition of chaos or non-integrability can be given in terms of the absence of conserved quantities necessary to yield a solution. It took several decades for the full significance of non-integrable dynamical systems to be appreciated and for the term “chaos” to be introduced (See **Chaotic dynamics**). An important step was the 1963 paper by Edward N. Lorenz, entitled “Deterministic Nonperiodic Flow” (Lorenz, 1963), on a model describing thermal convection in a layer of fluid heated from below. The Lorenz model truncates the basic fluid dynamical equations, written in terms of Fourier amplitudes, to just three modes (See **Lorenz**

equations):

$$\begin{aligned}\dot{x} &= -\sigma x + \sigma y, \\ \dot{y} &= -xz + rx - y \\ \dot{z} &= xy - bz.\end{aligned}\quad (1)$$

In this system, x is the time-dependent amplitude of a stream-function mode, while y and z are mode amplitudes of the temperature field. The parameters σ , r , and b depend on the geometry, the boundary conditions, and the physical parameters of the fluid. Equations (1) are a subset of the full, infinite system of mode amplitude equations, chosen such that it exactly captures the initial instability of the thermally conducting state to convecting rolls when the parameter r , known as the Rayleigh number, is increased.

What Lorenz observed in numerical solutions of (1), and verified by analysis, was that very complicated, erratic solutions would arise when r was increased well beyond the conduction-to-convection transition. In fact, Lorenz had found the first example of what is today called a strange attractor (See Figure 1 and **Attractors**). System (1) is clearly deterministic, yet it can produce non-periodic solutions. There were other intriguing aspects of the solutions to (1) in the chaotic regime. Solutions arising from close initial conditions would separate exponentially in time, leading to an apparently random dependence on initial conditions of the solution after a finite time (See **Butterfly effect**). Today, this would be associated with the existence of a positive characteristic Lyapunov exponent. A list of “symptoms” can be established that are shared by systems having the property of chaos, including: complex temporal evolution, exponential separation from close initial conditions, a strange attractor in phase space (if the system is dissipative), and positive Lyapunov exponents. An important difference from Poincaré’s work was that Lorenz’s system described a dissipative system in which energy is not conserved.

From the start, the potential connection between chaos and other concepts in statistical physics, such as ergodicity and turbulence, was of central interest. For example, chaos was thought to imply ergodic

Figure 1. Strange attractor associated with the Lorenz equations. Reproduced with permission from Images by Paul Bourke, <http://astronomy.swin.edu.au/pbourke/fractals/lorenz/>.

behavior in the sense of the “ergodic hypothesis” underlying equilibrium statistical mechanics (See **Ergodic theory**). Similarly, the connection between chaos and turbulence was sought, particularly appropriate given that Lorenz’s model was of a fluid flow. Experiments on other fluid systems by Gollub, Swinney, Libchaber, and later many others established that the transition from laminar to turbulent flow typically takes place through a regime of chaotic fluid motion. The well-known route to chaos via period-doubling bifurcations of Mitchell J. Feigenbaum belongs here as well (Feigenbaum, 1980; Eckmann, 1981). In view of this, it is natural to think that turbulent flow itself is simply some kind of chaotic flow state.

Turbulence is a common state of fluid flow that shares several “symptoms” with chaotic dynamical systems, but also has distinct features not easily duplicated by chaos. The word “turbulence” was apparently first used by Leonardo da Vinci to describe a complex flow. In mathematical terms, turbulent flows should be solutions of the Navier–Stokes equation, usually written in the dimensionless form (See **Navier–Stokes equation**)

$$\frac{\partial \mathbf{u}}{\partial t} + \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla p + R^{-1} \Delta \mathbf{u}, \quad (2)$$

$$\nabla \cdot \mathbf{u} = 0. \quad (3)$$

We have restricted attention to incompressible flows by insisting in (3) that the velocity field $\mathbf{u}(\mathbf{x}, t)$ be divergence free. In (2) the field p represents the pressure—the constant density has been absorbed in the nondimensionalization. The sole dimensionless parameter R is Reynolds number. In terms of physical variables $R = UL/\nu$, where U is a typical scale of velocity, L a typical length scale of the flow, and ν is the kinematic viscosity of the fluid. For small values of R , say $0 < R \leq 1$, the flow is laminar. For moderate R , say $1 < R \leq 100$, various periodic flow phenomena may arise, such as the shedding of vortices from blunt bodies. For large R , the flow eventually breaks down into many interacting eddies—this is turbulent flow. Since most flowing fluid is, in fact, flowing at large R , turbulence is the prevailing flow state of fluids in our surroundings (oceans and atmosphere), in the universe in general, in many industrial processes, and to some extent, within our bodies.

The characterization of what makes a flow turbulent is not nearly so clear as what makes a dynamical system chaotic. First, the issue of whether the particular set of nonlinear partial differential equations (2) and (3) even has a smooth solution for all time, given smooth initial conditions, is still unsettled and is one of the prize challenges set by the Clay Mathematics Institute (<http://www.claymath.org>). In spite of several attempts, a convincing example of a flow with smooth initial conditions, evolving under (2) and (3), that develops a singularity in a finite time has not been found.

Conversely, there is no proof that solutions with the requisite number of derivatives will exist for all time.

Turbulent flows are also recognized by a variety of “symptoms.” The flow velocity as a function of time at any given point in a turbulent flow is a random function (roughly a Gaussian). However, the overall nature of the velocity field viewed as a random vector field is not Gaussian. The random nature of turbulent velocity fields is today thoroughly familiar to the flying public. The randomness is not just temporal at a fixed point in space; the spatial variation of the flow field at a given time constitutes a multitude of interacting eddies of different sizes. Because of their random character, turbulent flows stir vigorously, leading to rapid dispersal of a passively advected substance or a field, such as temperature, and to a rapid exchange of momentum with contiguous fluid. In the classic pipe flow experiment of Osborne Reynolds, for example, in which the transition from laminar to turbulent flow was first demonstrated to depend only on the dimensionless number R , a streak of dye introduced at the inlet would remain a thin streak (except for a bit of molecular diffusion) when the flow in the pipe was laminar. When the flow rate was increased and the flow became turbulent, the dye rapidly dispersed across the pipe.

In a turbulent flow, the large scales of motion, which are typically in contact with some kind of forcing from the outside, will generate smaller scales through interactions and instabilities. This process continues through a broad range of length scales, ultimately reaching small scales where molecular dissipation is effective and quells the motion altogether. The repeated process of “handing down” energy from larger scales to smaller scales is a key process in turbulence. It is usually referred to as the Kolmogorov cascade (See **Kolmogorov cascade**). The qualitative nature of this process was already envisaged by Lewis Fry Richardson and was described by him in an adaptation of a verse by Jonathan Swift:

*Big whorls have little whorls,
Which feed on their velocity;
And little whorls have lesser whorls,
And so on to viscosity (in the molecular sense).*

Because of its broad range of length scales, the energy in a turbulent flow may be considered partitioned among modes of different wavenumbers k . The energy spectrum $E(k)$ is defined such that $E(k) dk$ is the amount of kinetic energy of the turbulent flow associated with motions with wavenumbers between k and $k + dk$. The cascade implies a transfer of energy from scale to scale with a characteristic energy flux per unit mass, ε , which must also be equal to the rate at which energy is fed to the flow from the largest scales, and to the rate at which energy is dissipated by viscosity at the smallest scales. A simple dimensional argument then (See **Dimensional**

analysis) gives the dependence of $E(k)$ on ε and k to be

$$E(k) = C\varepsilon^{2/3}k^{-5/3}. \quad (4)$$

This is the well-known Kolmogorov spectrum, predicted by Andrei N. Kolmogorov in 1941 (Hunt et al., 1991; Frisch, 1995) and only subsequently verified by experiments in a tidal channel (see Figure 2).

Turbulence has many further intriguing statistical properties, which remain subjects of active research. A major shift in our thinking on turbulence occurred in the late 1960s and in the 1970s when experiments by Kline and Brown & Roshko demonstrated that even in turbulent shear flows at very large Reynolds number, one can identify coherent structures that organize the flow to some extent (Figure 3). Later investigations have shown that even in homogeneous, isotropic turbulence,

Figure 2. One-dimensional spectrum in a tidal channel from data in Grant et al. (1962).

Figure 3. Coherent structures in a turbulent mixing layer. From Brown & Roshko (1974), reprinted from *An Album of Fluid Motion*, M. Van Dyke, Parabolic Press, 1982.

the flow is often organized into strong filamentary vortices. The persistence of these organized structures, which can dominate the flow for long times and interact dynamically, forces a strong coupling among the spectral modes, reducing the effective number of degrees of freedom of the problem.

Chaos and turbulence both describe states of a deterministic dynamical system in which the solutions appear random. Our current understanding of chaos is largely restricted to few-degree-of-freedom systems. Turbulence, on the other hand, is a many-degree-of-freedom phenomenon. It seems somewhat unique to fluid flows—related phenomena such as plasma turbulence or wave turbulence appear to be intrinsically different. The emergence of collective modes in the form of coherent structures in turbulence amidst the randomness is an intriguing feature, somewhat reminiscent of the mix between regular “islands” and the “chaotic sea” observed in chaotic, low-dimensional dynamical systems. The coherent structures themselves approximately form a deterministic, low-dimensional dynamical system. However, it seems impossible to fully eliminate all but a finite number of degrees of freedom in a turbulent flow—the modes not included explicitly form an essential, dissipative background, often referred to as an eddy viscosity, that must be included in the description.

Turbulence is intrinsically spatiotemporal, whereas chaotic behavior in a fluid system can be merely temporal with a simple spatial structure. It is possible for the flow field to be perfectly regular in space and time, yet the trajectories of fluid particles moving within the flow will be chaotic. This is the phenomenon of chaotic advection (*See Chaotic advection*), which points out the hugely increased complexity of a turbulent flow relative to chaos in a dynamical system.

CHAOTIC ADVECTION

In fluid mechanics, *advection* means the transport of material particles by a fluid flow, as when smoke from a chimney is blown by the wind. The term *passive advection* is sometimes used to emphasize that the substance being carried by the flow is sufficiently inert that it follows the flow entirely, the velocity of the advected substance at every point and every instant adjusting to that of the prevailing flow.

To describe the kinematics of a fluid, two points of view may be adopted: the Eulerian representation focuses on the velocity field $\mathbf{u}$ as a function of position and time, $\mathbf{u}(\mathbf{x}, t)$; the Lagrangian representation emphasizes the trajectories $\mathbf{x}_P(t)$ of a fluid particle as it is advected by the flow. The two points of view are linked by stating that the value of the velocity field at a given point in space and instant in time equals the velocity of the fluid element passing through that same point at that instant, that is,

$$\dot{\mathbf{x}}_P(t) = \mathbf{u}(\mathbf{x}_P(t), t). \quad (1)$$

The Eulerian representation is used extensively for measurements and numerical simulations of fluid flow since it allows one to fix the points in space and time where the field is to be determined. The Lagrangian representation, on the other hand, is often more natural for theoretical analysis, as it explicitly addresses the nonlinearity of the Navier–Stokes equation.

For a given flow, the equations of motion (1), sometimes called the *advection equations*, are a system of ordinary differential equations that define a dynamical system. These equations can be integrable or non-integrable. Chaotic advection appears when the equations are non-integrable and the trajectories of fluid elements become chaotic. The dynamical system defined by (1) has two or more degrees of freedom. For a two-dimensional time-independent or steady flow, there are just two degrees of freedom and no chaotic motion is possible. However, already for a 2-d time-dependent or a 3-d steady flow, there are enough degrees of freedom to allow for chaotic trajectories. In other words, chaotic advection can appear even for flows that would otherwise be considered laminar.

The phenomenon of chaotic advection is also known as Lagrangian chaos, or sometimes Lagrangian

turbulence. Usually, the word turbulence refers to the Eulerian representation and to flows in which the velocity field fluctuates across a wide range of spatial and temporal scales with limited correlations. In such flows, the trajectories of fluid elements are always chaotic. By contrast, chaotic advection or Lagrangian chaos can arise in situations where the velocity field is spatially coherent and the time dependence is no more complicated than a simple periodic modulation.

Many examples have now been given to illustrate the point that the complexity of the spatial structure of material advected by a flow can be much greater than one might surmise from a picture of the instantaneous streamlines of the flow. Thus, in the paper that introduced the notion of chaotic advection (Aref (1984) and Figure 1), the case of two stirrers that act alternately on fluid confined to a disk was considered. Each stirrer was modeled as a point vortex that could be switched on and off. There are several parameters in the system, such as the strengths and positions of the vortex stirrer and the time interval over which each acts. For a wide range of parameter values, the dynamics is as shown in Figure 1; after just a few periods, the 10,000 particles being advected are spread out over a large fraction of the disk.

Chaotic advection gives rise to very efficient stirring of a fluid. Material lines are stretched at a rate given by the Lyapunov exponent. In bounded flows, these exponentially growing material lines have to be folded back over and over again, giving rise to ever finer and denser striations. They are familiar from the mixing of paint or from marbled paper. On the smallest scales diffusion, takes over and smoothes the steep gradients, giving rise to mixing on the molecular scale. The interplay between stirring and diffusion is the

Figure 1. Spreading of 10,000 particles in a cylindrical container (disk) under the alternating action of two stirrers. The positions of the stirrers are marked by crosses. (a) initial distribution; (b)–(g) positions of the particles after 1, 2, ..., 6 periods; (h) after 9 periods; (i) after 12 periods. From (Aref, 1984).

source of the efficient mixing in the presence of chaotic advection. This phenomenon is being exploited in various procedures for mixing highly viscous fluids, including applications to materials processing, in micro-fluidics, and even in large-scale atmospheric, oceanographic, and geological flows. It may play a role in the feeding of microorganisms.

In the case of 2-d incompressible flows the equations of motion allow for an interesting connection to Hamiltonian dynamics. The velocity field can be represented through a stream function $\psi(x, y, t)$, so that $\mathbf{u} = \nabla \times \psi \mathbf{e}_z$ and Equations (1) for the trajectories of fluid elements become

$$\dot{x} = \frac{\partial \psi}{\partial y}, \quad \dot{y} = -\frac{\partial \psi}{\partial x}. \quad (2)$$

The relation to Hamilton's canonical equations is established through the identification x =position, y =momentum, and ψ =Hamilton function. Thus, what is the phase space in Hamiltonian systems can be visualized as the position space in the hydrodynamic situation. The structures that appear in 2-d periodically driven flows are, therefore, similar to the phase space structures in a Poincaré surface of section for a chaotic Hamiltonian system, and the same techniques can be used to analyze the transport of particles and the stretching and folding of material lines.

The phenomena that arise in chaotic advection by simple flows may be relevant to turbulent flows when a separation of length and time scales is possible. Consider, for example, the small-scale structures that appear in the density of a tracer substance when the molecular diffusivity κ of the tracer is much smaller than the kinematic viscosity ν of the liquid, that is, in a situation where the Schmidt number $Sc = \nu/\kappa$ is much larger than one. Then, the velocity field is smooth below the Kolmogorov scale, $\lambda_K = (\nu^3/\varepsilon)^{1/4}$, where ε is the kinetic energy dissipation, but the scalar field has structures on even smaller scales, down to $\lambda_s = (Sc)^{-1/2} \lambda_K$. These arise from Lagrangian chaos with a randomly fluctuating velocity field. The patterns produced in this so-called Batchelor regime are strikingly similar to the ones observed in laminar flows.

On larger scales, ideas from chaotic advection are relevant when there are large-scale coherent structures with slow spatial and temporal evolution. Typical examples are 2-d or quasi-2-d flows, for example, in the atmosphere or in the oceans. Fluid volumes can be trapped in regions bounded by separatrices or by stable and unstable manifolds of stagnation points and may have very little exchange with their surroundings. Such a reduction in stirring appears to occur in the Wadden sea (Ridderinkhof & Zimmerman, 1992).

Equations (1) apply in this form to fluid elements and ideal particles only. For realistic particles with finite volume and inertia, further terms must be added. A

significant change in the qualitative side is that the effective velocity field for inertial particles can have a nonvanishing divergence even for incompressible flows (Maxey & Riley, 1983).

The book by Ottino, (1989) and the two conference proceedings (Aref, 1994; IUTAM, 1991) provide good starting points for entering the many aspects of chaotic advection and Lagrangian chaos in engineering applications, geophysical flows, turbulent flows, and theoretical modeling. Historical remarks may be found in the Introduction to Aref, (1994) and in Aref, (2002). Today, the term chaotic advection designates an established subtopic of fluid mechanics that is used as a classification keyword by leading journals and conferences in the field.

CHAOTIC DYNAMICS

When we say “chaos”, we usually imagine a very complex scene with many different elements that move in different directions, collide with each other, and appear and disappear randomly. Thus, according to everyday intuition, the system's complexity (e.g., many degrees of freedom) is an important attribute of chaos. It seems reasonable to think that in the opposite case, for example, a system with only a few degrees of freedom, the dynamical behavior must be simple and predictable. In fact, this point of view is Laplacian determinism.

The discovery of dynamical chaos has destroyed this traditional view. Dynamical chaos is a phenomenon that can be described by mathematical models for many natural systems, for example, physical, chemical, biological, and social, which evolve in time according to a deterministic rule and demonstrate capricious and

seemingly unpredictable behavior. To illustrate such behavior, consider a few examples.

Examples

Hyperion: Using Newton’s laws, one can compute relatively easily all future solar eclipses not only for the next few hundred years but also for thousands and millions of years into the future. This is indicative of a real predictability of the system’s dynamical behavior. But even in the solar system, there exists an object with unpredictable behavior: a small irregularly shaped moon of Saturn, Hyperion. Its orbit is regular and elliptic, but its altitude in the orbit is not. Hyperion is tumbling in a complex and irregular pattern while obeying the laws of gravitational dynamics. Hyperion may not be the only example of chaotic motion in the solar system. Recent studies indicate that chaotic behavior possibly exists in Jovian planets (Murray & Holman, 1999), resulting from the overlap of components of the mean motion resonance among Jupiter, Saturn, and Uranus. Chaos in Hamiltonian systems, which represent the dynamics of the planets, arises when one resonance is perturbed by another one (See **Standard map**).

Chaotic mixing is an example of the complex irregular motion of particles in a regular periodic velocity field, like drops of cream in a cup of coffee; see Figure 1. Such mixing, caused by sequential stretching and folding of a region of the flow, illustrates the general mechanism of the origin of chaos in the phase space of simple dynamical systems (See **Chaotic advection**; **Mixing**).

Billiards: For its conceptual simplicity, nothing could be more deterministic and completely predictable

than the motion of a single ball on a billiard table. However, in the case of a table bounded by four quarters of a circle curved inward (Sinai billiard), the future fate of a rolling billiard ball is unpredictable beyond a surprisingly small number of bounces. As indicated by Figure 2, a typical trajectory of the Sinai billiard is irregular and a statistical approach is required for a quantitative description of this simple mechanical system. Such an irregularity is the result of having a finite space and an exponential instability of individual trajectories resulting in a sensitive dependence on initial conditions. Due to the curved shape of the boundary, two trajectories emanating from the same point but in slightly different directions with angle δ between them, hit the boundary $\partial\Omega$ (see Figure 2) at different points that are $c\delta$ apart where $c > 0$. After a bounce, the direction of the trajectories will differ by angle $(1 + 2c)\delta$, and because an actual difference between the directions is multiplied by a factor $\mu = (1 + 2c) > 1$, the small perturbation δ will grow more or less exponentially (Sinai, 2000). Such sensitive dependence on initial conditions is the main feature of every chaotic system.

A Markov map: To understand in more detail how randomness appears in a nonrandom system, consider a simple dynamical system in the form of a one-dimensional map

$$x_{n+1} = 2x_n \bmod 1. \tag{1}$$

Since the distance between any two nearby trajectories ($|x_n - x'_n| \ll 1$) after each iteration increases at least two times ($|dx_{n+1}/dx_n| = 2$), any trajectory of the map is unstable. The map has a countable infinity of unstable periodic trajectories, which can be seen as fixed points when one considers the shape of the map $x_{n+k} = F^{(k)}(x_n)$; see Figure 3(b). Since all fixed points and periodic trajectories are repelling, the only possibility left for the most arbitrarily selected initial condition is that the map will produce a chaotic motion that never exactly repeats itself. The irregularity of such dynamics can be illustrated using a binary symbolic description ($s_n = 0$ if $x_n < \frac{1}{2}$ and $s_n = 1$ if $x_n \geq \frac{1}{2}$). In this case, any value of x_n can be represented as a binary

Figure 1. Mixing of a passive tracer in a Newtonian flow between two rotating cylinders with different rotation axes. The rotation speed of the inner cylinder is modulated with constant frequency. The flow is stretched and folded in a region of the flow. The repetition of these operations leads to a layered structure—folds within folds, producing a fractal structure (Ottino, 1989).

Figure 2. Illustration of the trajectory sensitivity to the initial conditions in a billiard model with convex borders.

Figure 3. Simple map diagram: (a) two initially close trajectories diverge exponentially; (b) illustration of the increasing of the number of unstable periodic trajectories with the number of iterations.

decimal

$$x_n = 0.s_{n+1}s_{n+2}s_{n+3} \dots \equiv \sum_{j=n+1}^{\infty} 2^{-j} s_j.$$

If the initial state happens to be a rational number, it can be written as a periodic sequence of 0's and 1's. For instance, $0.1011101110111011\dots$ is the rational number $\frac{11}{15}$. Each iteration $x_n \rightarrow x_{n+1}$ of map (1) corresponds to setting the symbol s_{n+1} to zero and then moving the decimal point one space to the right (this is known as a *Bernoulli shift*). For example, the iterations of the number $\frac{11}{15}$ yield

$$\begin{aligned} &0.1011101110111011\dots, \\ &0.0111011101110110\dots, \\ &0.1110111011101101\dots, \\ &0.1101110111011101\dots, \\ &0.1011101110111011\dots, \end{aligned}$$

which illustrates a periodic motion of period 4. Selecting an irrational number as the initial condition, one chooses a binary sequence that cannot be split into groups of 0's and 1's periodically repeated an infinite number of times. As a result, each iteration of the

irrational number generates a new irrational number. Since the irrational numbers appear in the interval $x_n \in [0, 1]$ with probability one, one can observe only the aperiodic (chaotic) motions. Random-like behavior of the chaotic motions is illustrated in a separate figure in the color plate section (See the color plate section for a comparison of chaos generated by Equation (1) and a truly random process).

The degree of such chaoticity is characterized by *Lyapunov exponents* that can be defined for one-dimensional maps ($x_{n+1} = f(x_n)$). The stability or instability of a trajectory with the initial state x_0 is determined by the evolution of neighboring trajectories starting at $\tilde{x}_0 = x_0 + \delta x_0$ with $|\delta x_0| \ll 1$. After one iteration

$$\tilde{x}_1 = x_1 + \delta x_1 = f(x_0 + \delta x_0) \approx f(x_0) + \left. \frac{df}{dx} \right|_{x=x_0} \delta x_0.$$

Now, the deviation is $\delta x_1 \approx f'(x_0)\delta x_0$. After the n th iteration it becomes $\delta x_n = (\prod_{m=0}^{n-1} f'(x_m))\delta x_0$. The evolution of the distance between the two trajectories is calculated by taking the absolute value of this product. For infinitesimally small perturbations and large enough n , it is expected that $|\delta x_n| = \alpha^n |\delta x_0|$, where

$$\alpha \approx \lim_{n \rightarrow \infty} \left(\frac{|\delta x_n|}{|\delta x_0|} \right)^{1/n} = \left(\prod_{m=0}^{n-1} |f'(x_m)| \right)^{1/n}$$

or

$$\ln \alpha \approx \lambda = \lim_{n \rightarrow \infty} \frac{1}{n} \sum_{m=0}^{n-1} \ln (|f'(x_m)|). \quad (2)$$

Limit (2) exists for a typical trajectory x_m and defines the Lyapunov exponent, λ , which is the time average of the rate of exponential divergence of nearby trajectories. For map (1) $f' = 2$ for all values of x and, therefore, $\lambda = \ln 2$ (See **Lyapunov exponents**).

Assuming that the initial state cannot be defined with absolute accuracy, the prediction of the state of the map after a sufficiently large number of iterations becomes impossible. The only description that one can use for defining that state is a statistical one. The statistical ensemble in this case is the ensemble of initial conditions. The equation of evolution for the initial state probability density $\rho_{n+1}(F(x))$ can be written as (Ott, 1993, p. 33)

$$\rho_{n+1}(F(x)) = \sum_{j=1,2} \rho_n(x_j) \left| \frac{dF(x)}{dx} \right|_j, \quad (3)$$

where the summation is taken over both branches of $F(x)$. Considering the evolution of a sharp initial distribution $\rho_0(x)$, one can see that at each step this distribution becomes smoother. As n approaches infinity, the distribution asymptotically approaches the steady state $\rho(x) = 1$.

Figure 4. Bifurcation diagram for the logistic map.

Figure 5. Return map measured in the Belousov-Zhabotinsky autocatalytic reaction.

Population dynamics: A popular model of population growth is the logistic map $x_{n+1} = \alpha x_n(1 - x_n)$, $0 \leq \alpha \leq 4$ (See **Population dynamics**). The formation of chaos in this map is illustrated in the bifurcation diagram shown in Figure 4. This diagram presents the evolution of the attracting set as the value of α grows. Below the Feigenbaum point $\alpha_\infty = 3.569 \dots$, the attractor of the map is periodic. Its period increases through a sequence of period-doubling bifurcations as the value of α approaches α_∞ (See **Period doubling**). For $\alpha > \alpha_\infty$, the behavior is chaotic but some windows of periodic attractors exist (See **Order from chaos**).

Belousov-Zhabotinsky (BZ) autocatalytic reaction: In the BZ reaction (See **Belousov-Zhabotinsky reaction**), an acid bromate solution oxidizes malonic acid in the presence of a metal ion catalyst and other important chemical components in a well-stirred reactor (Roux et al., 1983). The concentration of the bromide ions is measured and parameterized by the return map (plotting a variable against its next value in time) $x_{n+1} = \alpha x_n \exp[-bx_n]$ (see Figure 5). This map exhibits chaotic behavior for a very broad range of parameter values.

Figure 6. Chaotic oscillation of a periodically driven pendulum, in phase-space plot of angular velocity versus angular position (Deco & Schürmann, 2000).

Figure 7. Ueda attractor. The fractal structure of the attractor is typical for all chaotic sets (compare this picture with Figure 1) (Ueda, 1992).

Simple chaotic oscillators: The dynamics of the periodically driven pendulum shown in Figure 6 is described by

$$\frac{d^2\Theta}{dt^2} + \nu \frac{d\Theta}{dt} + \frac{g}{l} \sin \Theta = B \cos 2\pi f t, \quad (4)$$

where the term on the right-hand side is the forcing (sinusoidal torque) applied to the pivot and f is the forcing frequency. Chaotic motions of the pendulum computed for $\nu = 0.5$, $g/l = 1$, $B = 1.15$, $f = 0.098$, and visualized with stroboscopic points at moments of time $t = i/f$ are shown in Figure 6.

A similar example of chaotic behavior was intensively studied in an oscillator where the restoring force is proportional to the cube of the displacement (Ueda, 1992, p. 158)

$$\frac{d^2\Theta}{dt^2} + \nu \frac{d\Theta}{dt} + \Theta^3 = B \cos t. \quad (5)$$

The stroboscopic image (with $t = i$) of the strange attractor in this forced Duffing-type oscillator computed with $\nu = 0.05$ and $B = 7.5$ is shown in Figure 7.

Figure 8. Chaotic attractor generated by electric circuit, which is a modification of van der Pol oscillator: $\dot{x} = hx + y - gz$; $\dot{y} = -x$; $\mu\dot{z} = x - f(x)$; where $f(x) = x^3 - x$ (Pikovsky & Rabinovich, 1978).

Figure 8 presents a chaotic attractor generated by an electronic circuit. Such circuits are a popular topic in engineering studies today.

Characteristics of Chaos

Lyapunov exponents: Consider the Lyapunov exponents for a trajectory $\tilde{x}(t)$ generated by a d -dimensional autonomous system

$$\frac{dx}{dt} = F(x), \quad (6)$$

with initial condition x_0 , $x \in \mathbb{R}^d$. Linearizing Equation (6) about this solution, one obtains a linear system which describes the evolution of infinitesimally small perturbations $w = x(t) - \tilde{x}(t)$ of the trajectory, in the form

$$\frac{dw}{dt} = M(\tilde{x})w, \quad (7)$$

where $M(x) = \partial F(x)/\partial x$ is the Jacobian of $F(x)$ that changes in time in accordance with $\tilde{x}(t)$. In d -dimensional phase space of (7), consider a sphere of initial conditions for perturbations $w(t)$ of diameter l , that is, $|w(0)| \leq l$. The evolution of this ball in time is governed by linear system (7) and depends on trajectory $\tilde{x}(t)$. As the system evolves in time, the ball transforms into an ellipsoid. Let the ellipsoid have d principal axes of different length l_j , $j = 1, d$. Then, the values of Lyapunov exponents of the trajectory $\tilde{x}(t)$ are defined as

$$\lambda_j(\tilde{x}) = \lim_{t \rightarrow \infty} \left[\left(\frac{1}{t} \right) \ln \left(\frac{l_j(\tilde{x}, t)}{l(x_0, 0)} \right) \right]. \quad (8)$$

Although limit (8) depends on $\tilde{x}(t)$, the *spectrum of the Lyapunov exponents* λ_j for the selected regime of

chaotic oscillations generated by (6) is independent of the initial conditions for the typical trajectories and characterizes the chaotic behavior.

The Lyapunov exponents, λ_j , can be ordered in size: $\lambda_1 \geq \lambda_2 \geq \dots \geq \lambda_d$. Self-sustained oscillations in autonomous time-continuous systems always have at least one Lyapunov exponent that is equal to zero. This is the exponent characterizing the stretching of phase volume along the trajectory. The spectrum of λ_j for chaotic trajectories contains one or more Lyapunov exponents with positive values.

Kolmogorov–Sinai entropy is a measure of the degree of predictability of further states visited by a chaotic trajectory started within a small region. Due to the divergence, a long-term observation of such a trajectory gives more and more information about the actual initial condition of the trajectory. In this sense, one may say that a chaotic trajectory creates information. Consider a partitioning of the d -dimensional phase space into small cubes of volume ε^d . Observing a continuous trajectory during T instances of time, one obtains a sequence $\{i_0, i_1, \dots, i_T\}$, where $i_0, i_1, \dots$ are the indexes of the cubes consequently visited by the trajectory. As a result, the type of the trajectory observed during the time interval from 0 to T is specified by the sequence $\{i_0, i_1, \dots, i_T\}$. As Kolmogorov and Sinai showed, in dynamical systems whose behavior is characterized by exponential instability, the number of different types of trajectories, K_T , grows exponentially with T :

$$0 < H = \lim_{T \rightarrow \infty} \frac{1}{T} \log K_T.$$

The quantity H is the Kolmogorov–Sinai (KS) entropy.

The number of unique random sequences $\{i_0, i_1, \dots, i_T\}$ that can be obtained without any rules applied increases exponentially with T . In the case of nonrandom sequences where there is a strict law for the generation of future symbols, like the periodic motion, the number of possible sequences grows in time slower than the exponent. Since the exponential growth takes place for the segments of trajectories in the unstable dynamical system producing chaos, such a dynamical system is capable of generating “random” sequences. The Kolmogorov–Sinai entropy is a measure of such “randomness” in a “nonrandom” system, for example, a dynamical system.

Since both KS entropy and Lyapunov exponents reflect the properties of the divergence of the nearby trajectories, these characteristics are related to each other. The formula describing this relation is given by Ruelle’s Inequality

$$H \leq K = \sum_{j=1}^m \lambda_j \geq 0 \quad (9)$$

where m is the number of positive λ_i ($K=0$, when $m=0$). The equality $H=K$ holds when the system

has a physical measure (Sinai–Ruelle–Bowen measure) (Young, 1998). The invariant set of trajectories characterized by a positive Kolmogorov–Sinai entropy is a chaotic set.

Forecasting

If a sufficiently long experimental time series capturing the chaotic process of an unknown dynamical system is available in the form of scalar data $\{x_n\}_{n=0}^N$, it is possible, in principle, to predict x_{N+m} with finite accuracy for some $m \geq 1$. Such predictions are based on the assumption that the unknown generating mechanism is time independent. As a result, “what happened in the past may happen again—even stronger: that what is happening now has happened in the past” (Takens, 1991). In classical mechanics (no dissipation), this idea of “what happens now has happened in the past” is related to the Poincaré Recurrence Theorem.

Usually, the prediction procedure consists of two steps: first, it is necessary to consider all values of n in the “past,” that is, with $n < N$, such that $\sum_{k=0}^K |x_{n-k} - x_{N-k}| < \varepsilon$, where ε is a small constant. If there are only a few of such n , then one can try again with a smaller value of K or a larger value of ε . In the second step, it is necessary to consider the corresponding elements x_{n+l} for all the values of n found in the first step. Finally, taking a union of the ε -neighborhoods of all these elements, one can predict that x_{N+l} will be in this union.

To understand when and why forecasting is possible and when it is not, it is reasonable to use characteristics such as *dimension* and *entropy* that can be computed directly from time series (Takens, 1991). If we want to make a catalog of essentially different segments of length $k+1$ in $\{x_n\}_{n=0}^N$, this can be done with $C(k, \varepsilon, N)$ elements. $C(k, \varepsilon, N)$ is a function of N that has a limit $C(k, \varepsilon) = \lim_{N \rightarrow \infty} C(k, \varepsilon, N)$, and for prediction, we need $C(k, \varepsilon) \ll N$.

The quantitative measure for the way in which $C(k, \varepsilon)$ increases as ε goes to zero is

$$D = \lim_{k \rightarrow \infty} \left(\lim_{\varepsilon \rightarrow 0} \frac{C(k, \varepsilon, N)}{\ln(1/\varepsilon)} \right). \quad (10)$$

If D is large, the prediction is problematic. The quantity D defined by (10) is the dimension of the time series.

The quantitative measure for the way in which $C(k, \varepsilon)$ increases with k is

$$H = \overline{\lim}_{\varepsilon \rightarrow 0} \left(\lim_{k \rightarrow \infty} \frac{C(k, \varepsilon, N)}{k} \right), \quad (11)$$

This is the entropy of the time series. For the time series generated by a differentiable dynamical system, both the dimension and entropy are finite, but for a random time series they are infinite. Suppose each x_n is taken at

random in the interval $[0, 1]$ (with respect to the uniform distribution) and for each $n_1, \dots, n_k$ (different), the choices of $x_{n_1}, \dots, x_{n_k}$ are independent. For such time series, one can find: $C(k, \varepsilon) = (1 + \lfloor 1/2\varepsilon \rfloor)^{k+1}$, where $\lfloor 1/2\varepsilon \rfloor$ is the integer part of $1/2\varepsilon$. From this formula, it immediately follows that both dimension and entropy in such random time series are infinite.

Models of the Earth’s atmosphere are generally considered as chaotic dynamical systems. Due to the instability, even infinitesimally small uncertainties in the initial conditions grow exponentially fast and make a forecast useless after a finite time interval. This is known as the butterfly effect. However, in the tropics, there are certain regions where wind patterns and rainfall are so strongly determined by the temperature of the underlying sea surface, that they do not show such sensitive dependence on the atmosphere. Therefore, it should be possible to predict large-scale tropical circulation and rainfall for as long as the ocean temperature can be predicted (Shukla, 1998).

History

The complex behavior of nonlinear oscillatory systems was observed long before dynamical chaos was understood. In fact, the possibility of complex behavior in dynamical systems was discovered by Henri Poincaré in the 1890s in his unsuccessful efforts to prove the regularity and stability of planetary orbits. Later on, experiments with an electrical circuit by van der Pol and van der Mark (1927) and the double-disk model experiments of the magnetic dynamo (Rikitake, 1958) also indicated the paradoxically complex behavior of a simple system. At that time, several mathematical tools were available to aid the description of the nontrivial behavior of dynamical systems in phase space, such as homoclinic Poincaré structures (homoclinic tangles). However, at the time, neither physicists nor mathematicians realized that deterministic systems may behave chaotically. It was only in the 1960s that the understanding of randomness was revolutionized as a result of discoveries in mathematics and in computer modeling (Lorenz, 1963) of real systems. An elementary model of chaotic dynamics was suggested by Boris Chirikov in 1959. During the last few decades, chaotic dynamics has moved from mystery to familiarity.

Standard map and homoclinic tangle: The standard map (Chirikov, 1979) is an area-preserving map

$$\begin{aligned} I_{n+1} &= I_n + K \sin \Theta_n, \\ \Theta_{n+1} &= I_n + \Theta_n + K \sin \Theta_n, \end{aligned} \quad (12)$$

where Θ is an angle variable (computed modulo 2π) and K is a positive constant. This map was proposed as a model for the motion of a charged particle in a magnetic field. For K larger than K_{cr} , map

Figure 9. Examples of chaos in the standard map for two different values of K . The coexistence of the “chaotic sea” and “regular islands” that one can see in the panel on the right is typical for Hamiltonian systems with chaotic regimes (Lichtenberg & Lieberman, 1992).

(12) demonstrates an irregular (chaotic) motion; see Figure 9. The complexity of the phase portrait of this map is related to the existence of *homoclinic tangles* formed by stable and unstable manifolds of a saddle point or saddle periodic orbits when the manifolds intersect transversally. The complexity of the manifold’s geometry stems from the fact that, if stable and unstable manifolds intersect once, then they must intersect an infinite number of times. Such a complex structure results in the generation of a horseshoe mapping, which persistently stretches and then folds the area around the manifolds generating a chaotic motion. The layers of the chaotic motion are clearly seen in Figure 9.

Lorenz system: The first clear numerical manifestation of chaotic dynamics was obtained in the Lorenz model. This model is a three-dimensional dynamical system derived from a reasonable simplification of the fluid dynamics equations for thermal convection in a liquid layer heated from below. The differential equations $\dot{x} = \sigma(y - x)$, $\dot{y} = rx - y - xz$, $\dot{z} = -bz + xy$

are written for the amplitude of the first horizontal harmonic of the vertical velocity (x), the amplitude of the corresponding temperature fluctuation (y), and a uniform correction of the temperature field (z) (Lorenz, 1963). σ is the Prandtl number, r is the reduced Rayleigh number, and b is a geometric factor. The phase portrait of the Lorenz attractor, time series, and the return mapping generated on the Poincaré cross section computed for $r = 28$, $\sigma = 10$, and $b = \frac{8}{3}$ are presented in Figure 10. A simple mechanical model illustrating the dynamical origin of oscillations in the Lorenz system is shown in Figure 11 (See **Lorenz equations**).

Definition of Chaos

As was shown above, dynamical chaos is related to unpredictability. For quantitative measurement of the unpredictability, it is reasonable to use the familiar characteristics *dimension* and *entropy*. These characteristics are independent: it is possible to generate a time series that has a high dimension and at the same time entropy equal to zero. This is a quasi-periodic motion. It is also simple to imagine a low-dimensional dynamical system with high entropy (see, e.g., the map in Figure 3).

Various definitions of chaos exist, but the common feature of these definitions is the sensitive dependence on initial conditions that was formalized above as positive entropy. Thus, dynamical chaos is the behavior of a dynamical system that is characterized by finite positive entropy.

Chaotic Attractors and Strange Attractors

A region in the phase space of a dissipative system that attracts all neighboring trajectories is called an attractor. An attractor is the phase space image of the behavior established in the dissipative system, for example, a stable limit cycle is the image of periodic oscillations. Therefore, the image of chaotic oscillations is a chaotic attractor.

A *chaotic attractor* (CA) possesses the following two properties that define any attractor of the dynamical system:

- There exists a bounded open region U containing a chaotic attractor ($CA \in U$) in the phase space such that all points from this neighborhood converge to a chaotic attractor when time goes to infinity.
- A chaotic attractor is invariant under the evolution of the system,

In addition, the motion on a chaotic attractor has to be chaotic, for example:

- each trajectory of a chaotic attractor has at least one positive Lyapunov exponent.

Such types of attractors represent some regimes of chaotic oscillations generated by a Lorenz system and

Figure 10. Lorenz attractor (left) and the return map $z_{n+1} = F(z_n)$ plotted for maximum values of variable z for the attractor trajectory (right).

Figure 11. A toy model invented by Willem Malkus and Lou Howard illustrates dynamical mechanisms analogous to oscillations and chaos in the Lorenz system. Water steadily flowing into the top (leaky) bucket makes it heavy enough to start the wheel turning. When the flow is large enough, the wheel can start generating chaotic rotations characterized by unpredictable switching of the rotation direction; see Strogatz (1994, p. 302) for details.

the piece-wise linear maps. However, most of the chaotic oscillations observed in dynamical systems correspond to attractors that do not precisely satisfy the latter property. Although almost all trajectories in such attractors are unstable, some stable periodic orbits may exist within the complex structure of unstable trajectories. Chaos in such systems is persistent both in physical experiments and in numerical simulations because all of these stable orbits have extremely narrow basins of attraction. Due to natural small perturbations of the system, the trajectory of the system never settles down on one of the stable orbits and wanders within the complex set of unstable orbits.

The definition of a *strange attractor* is related to the complicated geometrical structure of an attractor. A strange attractor is defined as an attractor that cannot be presented by a union of the finite number of smooth manifolds. For example, an attractor whose topology can be locally represented by the direct product of a Cantor set to a manifold is a strange attractor. In many cases, the geometry of a chaotic attractor satisfies the definition of a strange attractor. At the same time, the definition of a strange attractor can be satisfied in the case of a nonchaotic strange attractor. This is an

attractor that has fractal structure, but does not have positive Lyapunov exponents.

The origin of chaotic dynamics in dissipative systems and Hamiltonian systems in many cases is the same and is related to coexistence in the phase space of infinitely many unstable periodic trajectories as a part of homoclinic or heteroclinic tangles.

The Lorenz attractor, as for many other attractors in systems with a small number of degrees of freedom, can appear through a finite number of easily observable bifurcations. The bifurcation of a sudden birth and death of a strange attractor is called a crisis. Usually, it is related to the collision of the attractor with an unstable periodic orbit or its stable manifold (Arnol'd et al., 1993; Ott, 1993).

Order in Chaos

How does the dynamical origin imprint in chaos? Or in other words, how can the rules or order of the dynamical system be found inside a chaotic behavior? Consider the images (portraits) of the dynamical chaos shown in Figures 7, 8, and 10. The elegance of these images reflects the existence of order in dynamical chaos.

The dynamical origin of such elegance is very similar: different trajectories with close initial conditions have to be close in time $t_l \approx 1/\lambda$, where λ is the maximally positive Lyapunov exponent. The domain occupied by the strange attractor in phase space is finite; thus, the divergence of the phase space flow changes to convergence, and as a result of sequential action of divergence and convergence of the phase flow in the finite domain, the mixing of trajectories occurs. Such mixing can be illustrated with the motions of liquids in the physical space experimentally observed by Ottino (1989; see Figure 1).

Another way to recognize the existence of order in chaos is to analyze its dependence on a control parameter. The macroscopic features of real stochastic

Figure 12. Appearance of spatiotemporal chaos in the extended Faraday experiment: chaotic patterns on the surface of the liquid layer in the oscillating gravitational field. The irregular chain of the localized structures—dark solitons—can be seen beneath a background of the square capillary lattice (Gaponov-Grekhov & Rabinovich, 1988).

processes, for example, Brownian motion or developed turbulence, depend on this parameter and change without any revolutionary events such as bifurcations. But for dynamical chaos, the picture is different. A continuous increase of control parameters of the logistic map does not necessarily gradually increase the degree of chaos: within chaos, there are windows—intervals of control parameter values in which the chaotic behavior of the system changes to stable periodic behavior, see Figure 4.

In a spatially extended system, for example, in convection or Faraday flow, order within chaos is related to the existence of coherent structures inside the chaotic sea (Rabinovich et al., 2001); see Figure 12.

Spatiotemporal Chaos

Similar to regular (e.g., periodic) motions, low-dimensional chaotic behavior is observed not only in simple (e.g., low-dimensional) systems but also in systems with many, and even with infinite number of degrees of freedom. The dynamical mechanisms behind the formation of low-dimensional chaotic spatiotemporal patterns in dissipative and nondissipative systems are different. In conservative systems, such patterns are related to the chaotic motion of particle-like localized structures. For example, a soliton that is described by a nonlinear Schrödinger equation with the harmonic potential

$$i \frac{\partial a}{\partial t} + \beta \frac{\partial^2 a}{\partial^2 x} + (|a|^2 + \alpha \sin qx) a = 0 \quad (13)$$

Figure 13. Dynamics of chaotic bursts of spikes generated by two living neurons coupled with an electrical synapse—a gap junction (Elson et al., 1998). Chaotic bursts in naturally coupled neurons synchronize (a). When natural coupling is compensated by additional artificial coupling g_a , the chaotic oscillations are independent oscillations (b). The neurons coupled with negative conductivity fire in the regimes of antiphase synchronization (c).

moves chaotically in physical space x and reminds us of the chaotic motion occurring in the phase space of a parametrically excited conservative oscillator (the equations of such an oscillator can be derived from (13) for slow variables characterizing the motion of the soliton center mass).

The interaction of the localized structures (particles) in a finite area, large in comparison with the size of the structure, can also lead to the appearance of spatiotemporal chaos. It was observed that collisions of solitons moving in two-dimensional space result in chaotic scattering similar to the chaotic motion observed in billiards (Gorshkov et al., 1992).

In dissipative nonlinear media and high-dimensional discrete systems, the role of coherent structures is also very important (such as defects in convection, clusters of excitations in neural networks, and vortices in the wake behind a cylinder; see Rabinovich et al., 2001). However, the origin of low-dimensional chaotic motions in such systems is determined by dissipation. There are two important mechanisms of finite dynamics (including chaos) that are due to dissipation: (1) the truncation of the number of excited modes (in hydrodynamic flows) due to high viscosity of the small-scale perturbations and (2) the synchronization of the modes or individual oscillators. Dissipation makes synchronization possible not only among periodic modes or oscillators but even in the case when the interacting subsystems are chaotic (Afraimovich et al., 1986). Figure 13 illustrates the synchronization of chaotic bursts of spikes observed experimentally in two coupled living neurons. In the case of a dissipative lattice of chaotic elements (e.g., neural lattices or models of an extended autocatalytic chemical reaction), complete synchronization leads to the onset

Figure 14. Coherent patterns generated in the chaotic medium with Rössler-type dynamics of medium elements. Left: an example of coherent patterns with defects. Right: evolution of the attractor with increasing distance r from a defect. The attractor changed from the limit cycle of period T at $r = r_1$ to the period $2T$ limit cycle at $r = r_2 > r_1$, then to the period $4T$ limit cycle at $r = r_3 > r_2$, and finally to the chaotic attractor for $r = r_4 > r_3$ (Goryachev & Kapral, 1996).

of a spatially homogeneous chaotic state. When this state becomes unstable against spatial perturbations, the system moves to the spatiotemporal chaotic state. A snapshot of such spatiotemporal chaos, which is observed in the model of chaotic media consisting of diffusively coupled Rössler-type chaotic oscillators, is presented in Figure 14. Figure 14 also illustrates the sequence of period-doubling bifurcations that are observed in the neighborhood of the defect in such a medium.

Edge of Chaos

In dynamical systems with many elements and interconnections (e.g., complex systems), the transition between ordered dynamics and chaos is similar to phase transitions between states of matter (crystal, liquid, gas, etc.). Based on this analogy, an attractive hypothesis named “edge of chaos”(EOC) appeared at the end of the 1980s. EOC suggests a fundamental equivalence between the dynamics of phase transitions and the dynamics of information processing (computation). One of the simplest frameworks in which to formulate relations between complex system dynamics and computation at the EOC is a cellular automaton. There is currently some controversy over the validity of this idea (Langton 1990; Mitchel et al., 1993).

Chaos and Turbulence

The discovery of dynamical chaos has fundamentally changed the accepted concept of the origin of hydrodynamic turbulence. When dealing with turbulence at

finite Reynolds number, the main point of interest is the established irregular motion. The image of such irregularity in the phase space could be a chaotic attractor. Experiments in closed systems, for example, one in which fluid particles continuously recirculate through points previously visited, have shown the most common scenarios for the transition to chaos. These are (i) transition through the destruction of quasiperiodic motion that was observed in Taylor–Couette flow (Gollub & Swinney, 1975); (ii) period-doubling sequence observed in Rayleigh–Bénard convection (Libchaber & Maurer, 1980); and (iii) transition through intermittency (Gollub & Benson, 1980). Observation of these canonical scenarios for particular flows proved the validity of the concept of dynamical origin of the transition to turbulence in closed systems. It is possible to reconstruct a chaotic set in the phase space of the flow directly from observed data; see Brandstätter et al. (1982). At present it is difficult to say how dynamical chaos theory can be useful for the understanding and description of the developed turbulence.

The discovery and understanding of chaotic dynamics have important applications in all branches of science and engineering and, in general, to our evolving culture. An understanding of the origins of chaos in the last decades has produced many clear and useful models for the description of systems with complex behavior, such as the global economy (Barkly Russel, 2000), the human immune system (Gupta et al., 1998), animal behavior (Varona et al., 2002), and more. Thus, chaos theory provides a new tool for the unification of the sciences.

CHARACTERISTICS

Systems of first-order partial differential equations describe many different physical phenomena from the behavior of fluids, gases, and plasmas. To introduce the Method of Characteristics, consider the simple scalar conservation law of the form

$$\frac{\partial U}{\partial t} + A(U) \frac{\partial U}{\partial x} = 0. \quad (1)$$

Here, $U = U(x, t)$, where x is a spatial coordinate and t is the time coordinate. The function $A(U)$ defines the speed of propagation of a disturbance and either may be independent of U , in which case equation (1) is a linear partial differential equation, or it may depend explicitly on the dependent variable U , in which case the equation is a nonlinear partial differential equation.

It is important to specify the initial or boundary conditions that the solution $U(x, t)$ must satisfy.

Consider the simple case where the function is known at the initial time $t = 0$. Thus,

$$U(x, 0) = F(x). \quad (2)$$

The idea is to simplify Equation (1) by choosing a suitable curve in the x - t plane. This curve can be written in parametric form as

$$x = x(s), \quad t = t(s), \quad (3)$$

where s is the parameter that can be thought of as measuring the distance along the curve. To understand how to select the particular form of the curve, note that, using (3),

$$U(x, t) = U(x(s), t(s)), \quad (4)$$

implies that U is a function of s . Hence, the chain rule gives the derivatives of U along the curve as

$$\frac{dU}{ds} = \frac{\partial U}{\partial t} \frac{dt}{ds} + \frac{\partial U}{\partial x} \frac{dx}{ds}. \quad (5)$$

Comparing the right-hand side of (5) with the left-hand side of (1), it is clear that they are identical, provided the parametric form of the curve is chosen as

$$\frac{dt}{ds} = 1, \quad (6)$$

$$\frac{dx}{ds} = A(U), \quad (7)$$

and (1) reduces to

$$\frac{dU}{ds} = 0, \Rightarrow U = \text{constant along the curve.} \quad (8)$$

The curve satisfied by (6) and (7) is called the *characteristic curve*. Along this curve, U is constant. However, the value of the constant may be different on each characteristic curve. The solution of the characteristic equations requires some initial conditions for x and t . These are taken as

$$x = x_0, \quad t = 0, \quad \text{at } s = 0. \quad (9)$$

Note that x_0 covers the same domain as x . Solving (6)–(8) yields

$$t = s, \quad x = A(U)s + x_0, \quad (10)$$

on using the initial conditions (9). x_0 can be thought of as a constant of integration and so it has a fixed value along the characteristic curve. This implies, using (2), that

$$U(x, 0) = F(x_0). \quad (11)$$

Note that the particular characteristic curve is determined by the value of the parameter x_0 . Hence, eliminating the parameter s and solving for x_0 in terms of x , U , and t , the solution given by (11) is

$$U(x, t) = F(x_0) = F(x - A(U)t). \quad (12)$$

If $A(U)$ is a constant, say c , then the solution is simply

$$U(x, t) = F(x - ct), \quad (13)$$

but if $A(U)$ depends explicitly on U , then the solution is an *implicit solution*.

The characteristic curves in this example are straight lines in the x - t plane with a gradient given by $A(U)$. When $A(U) = c$ is a constant, the characteristic curves are parallel straight lines. This means that the shape of the initial disturbance propagates unchanged, to the right if c is a positive constant. If $A(U)$ depends on U , then the characteristic curves are straight lines but with different gradients. There exists the possibility that the characteristic curves may cross, and this corresponds to the formation of a shock. When the characteristic curves diverge, the solution exhibits an expansion fan that can be expressed in terms of a similarity variable.

Note that the method of characteristics can be used when $A = A(U, x, t)$ depends explicitly on the space and time coordinates. In this case, the coupled equations, (6)–(8), may be solved numerically. A detailed description of the method of characteristics for general first-order partial differential equations is given in Rubenstein & Rubenstein (1993).

Example: Burgers Equation

Consider the case when $A(U) = U$. Then, (1) becomes the inviscid Burgers equation

$$\frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} = 0, \quad (14)$$

and the solution satisfying the initial condition

$$U(x, 0) = \begin{cases} 0, & x < -1, \\ 1+x, & -1 \leq x < 0, \\ 1-x, & 0 \leq x \leq 1, \\ 0, & x > 1 \end{cases} \quad (15)$$

is

$$U = \begin{cases} 0, & x < -1 + Ut, \\ 1+x-Ut, & -1+Ut \leq x < Ut, \\ 1-x+Ut, & Ut \leq x \leq 1+Ut, \\ 0, & x > 1+Ut. \end{cases} \quad (16)$$

Thus, solving for U in each region gives the solution as

$$U = \begin{cases} 0, & x < -1, \\ (1+x)/(1+t), & -1 \leq x < t, \\ (1-x)/(1-t), & t \leq x \leq 1, \\ 0, & x > 1. \end{cases} \quad (17)$$

Note that the solution becomes multi-valued for $t > 1$. This can be understood by considering the characteristic curves defined by (9). In the x - t plane, they are straight lines of the form

$$x = Ut + x_0, \quad (18)$$

so that the gradient depends on the value of U at $t = 0$ and $x = x_0$. Thus, using the initial conditions, the characteristic curves, valid in the region $t \leq x \leq 1$, can be expressed as

$$x = (1 - x_0)t + x_0, \quad (19)$$

for $0 \leq x_0 \leq 1$. Considering two different values of x_0 , say x_a and x_b , the straight lines cross when

$$\begin{aligned} x &= (1 - x_a)t + x_a = (1 - x_b)t + x_b, \\ \Rightarrow \quad t &= 1 \quad \text{and} \quad x = 1. \end{aligned} \quad (20)$$

Hyperbolic Systems of Several Dependent Variables

Systems of first-order hyperbolic equations can be expressed in vector and matrix form as

$$\frac{\partial \mathbf{U}}{\partial t} + \mathbf{A}(\mathbf{U}, x, t) \frac{\partial \mathbf{U}}{\partial x} = 0, \quad (21)$$

where $\mathbf{U}$ is a column vector of n elements containing the dependent variables and $\mathbf{A}$ is an $n \times n$ matrix whose coefficients may depend on the dependent variables. The problem is linear if the matrix $\mathbf{A}$ has elements independent of $\mathbf{U}$ and nonlinear otherwise. The characteristic curves in this case are given by the equations

$$\frac{dt}{ds} = 1, \quad (22)$$

$$\frac{dx}{ds} = \lambda_i(\mathbf{U}, x, t) \quad (23)$$

for $i = 1, 2, \dots, n$ and where λ_i is an eigenvalue of the matrix $\mathbf{A}$. Here, it is assumed that the matrix $\mathbf{A}$ has n distinct eigenvalues. For the linear problem, and in particular, for the case where the matrix $\mathbf{A}$ has constant coefficients, the full solution can be obtained by using a suitable linear combination of dependent variables so that the equations reduce to a set of simple advection equations. Hence, the first step is to determine the eigenvalues, λ_i , of the matrix $\mathbf{A}$ and the corresponding eigenvectors $\mathbf{z}_i$, where

$$\mathbf{A}\mathbf{z}_i = \lambda_i\mathbf{z}_i, \quad (24)$$

Next, use the change of variable

$$\mathbf{U} = \mathbf{Q}\mathbf{V}, \quad (25)$$

where $\mathbf{Q}$ is an $n \times n$ matrix whose j th column is the j th eigenvector $\mathbf{z}_j$. Substituting into (21) yields

$$\mathbf{Q} \frac{\partial \mathbf{V}}{\partial t} + \mathbf{A}\mathbf{Q} \frac{\partial \mathbf{V}}{\partial x} = 0. \quad (26)$$

Finally, pre-multiplying by $\mathbf{Q}^{-1}$, the inverse of $\mathbf{Q}$, results in a decoupled system of equation, since $\mathbf{Q}^{-1}\mathbf{A}\mathbf{Q}$ is a diagonal matrix whose elements are the eigenvalues λ_i . Thus, the final set of n equations are

$$\frac{\partial V_i}{\partial t} + \lambda_i \frac{\partial V_i}{\partial x} = 0, \quad (27)$$

for $i = 1, 2, \dots, n$. The solutions to (27) are simply

$$V_i = F_i(x - \lambda_i t), \quad (28)$$

where F_i is an arbitrary function determined by the initial conditions. Once all the solutions for V_i are determined from the initial conditions, the solution in terms of the original variables is obtained using (25). Note that while the original variables may depend on all the characteristic variables, the V_i solution is *constant* along the i th characteristic curve.

Example: The Second-Order Wave Equation

The second-order wave equation

$$\frac{\partial^2 U}{\partial t^2} = c^2 \frac{\partial^2 U}{\partial x^2} \quad (29)$$

can be expressed as a pair of first-order equations as

$$\begin{aligned} \frac{\partial U}{\partial t} &= -c \frac{\partial p}{\partial x}, \\ \frac{\partial p}{\partial t} &= -c \frac{\partial U}{\partial x}. \end{aligned}$$

Thus,

$$\mathbf{A} = \begin{pmatrix} 0 & c \\ c & 0 \end{pmatrix}. \quad (30)$$

The eigenvalues are simply $\lambda_1 = c$ and $\lambda_2 = -c$ and the corresponding eigenvectors are

$$\mathbf{z}_1 = \begin{pmatrix} 1 \\ -1 \end{pmatrix}, \quad \mathbf{z}_2 = \begin{pmatrix} 1 \\ 1 \end{pmatrix}. \quad (31)$$

Thus,

$$\mathbf{Q} = \begin{pmatrix} 1 & 1 \\ -1 & 1 \end{pmatrix}, \quad \mathbf{Q}^{-1} = \frac{1}{2} \begin{pmatrix} 1 & -1 \\ 1 & 1 \end{pmatrix}. \quad (32)$$

Equation (27) reduces to the pair of equations

$$\frac{\partial V_1}{\partial t} - c \frac{\partial V_1}{\partial x} = 0, \quad \frac{\partial V_2}{\partial t} + c \frac{\partial V_2}{\partial x} = 0. \quad (33)$$

The solutions are $V_1 = F_1(x + ct)$ and $V_2 = F_2(x - ct)$ and, in terms of the original variables, the solution is

$$\begin{aligned} U &= F_1(x + ct) + F_2(x - ct), \\ p &= -F_1(x + ct) + F_2(x - ct). \end{aligned} \quad (34)$$

Riemann Invariants

A Riemann invariant may be thought of as a function of the dependent variables that is constant along a characteristic curve. In the previous example, it is clear that $U + p = 2F_2(x - ct)$, so $U + p$ is a Riemann invariant along the characteristic curve defined by $x - ct = \text{constant}$. Similarly, $U - p$ is constant along $x + ct = \text{constant}$.

Example: Isentropic Flow

The dimensionless equations for *isentropic* fluid flow with $p/\rho^\gamma = 1$ can be expressed in terms of the fluid velocity, u , and the sound speed $c = (\gamma p/\rho)^{1/2}$ as

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + \frac{2}{\gamma - 1} c \frac{\partial c}{\partial x} = 0, \quad (35)$$

$$\frac{\partial c}{\partial t} + \frac{\gamma - 1}{2} c \frac{\partial u}{\partial x} + u \frac{\partial c}{\partial x} = 0. \quad (36)$$

A detailed derivation of these equations is given in Kevorkian (1989). The matrix A is

$$A = \begin{pmatrix} u & \frac{2}{\gamma - 1} c \\ \frac{\gamma - 1}{2} c & u \end{pmatrix} \quad (37)$$

having eigenvalues $\lambda_1 = u + c$ and $\lambda_2 = u - c$. There are two characteristic curves given by the solution of the coupled differential equations

$$\begin{aligned} \frac{dt}{ds} &= 1, \\ \frac{dx}{ds} &= \lambda_i, \end{aligned}$$

where $i = 1$ or $i = 2$. For $i = 1$, the initial conditions are $t = 0$ and $x = \xi$ at $s = 0$, which implies that the characteristic curve is defined by $\xi = x - \int_0^t (u + c) ds = \text{constant}$. For $i = 2$, $t = 0$, and $x = \eta$ at $s = 0$, the second curve is defined by $\eta = x - \int_0^t (u - c) ds = \text{constant}$. Multiplying (35) by $(\gamma - 1)/2$ and then adding and subtracting (36) gives two equations

$$\begin{aligned} \frac{\partial R}{\partial t} + (u + c) \frac{\partial R}{\partial x} &= 0, \\ \frac{\partial S}{\partial t} + (u - c) \frac{\partial S}{\partial x} &= 0, \end{aligned}$$

where $R = c + (\gamma - 1)u/2$ and $S = c - (\gamma - 1)u/2$. R and S are Riemann invariants since R is constant along

the characteristic curve defined by $\xi = \text{constant}$ and S is constant along $\eta = \text{constant}$. A more detailed derivation of Riemann invariants is described in Kevorkian (1989).

CHARGE DENSITY WAVES

A charge density wave (CDW) is a collective transport phenomenon, whose origin lies in the interaction between electrons and phonons in a solid (Grüner & Zettl 1985; Grüner, 1988). As envisioned by Rudolph Peierls in 1930 in some quasi-one-dimensional metals (where the influence of one electron to each other electron is much stronger than in higher dimensions), the elastic energy needed to displace the position of the atoms may be balanced by a lowering of conduction electron energy.

In such cases, the more stable configuration may have a periodic distortion of the lattice; thus, there is a modulation of the electronic charge density, which gives rise to a CDW. The wave vector turns out to be $Q = 2k_F$, where k_F is the Fermi wave vector, and the electronic density becomes

$$\delta\rho = \rho_0 \cos(2k_F x + \phi).$$

Due to this periodic lattice distortion, a gap at the Fermi level appears, and the conduction electrons lower their kinetic energy. At high temperatures, thermal excitation of electrons across the band gap makes the normal metallic state stable. When the temperature is sufficiently low, a second-order phase transition (known as the Peierls transition) takes place, and a CDW is formed.

In 1954, Herbert Fröhlich suggested that if Q was not commensurate with the lattice constant, the CDW energy would be independent of the phase ϕ , and thus, an electrical current would appear under any electric field, independent of its intensity. For a while, this phenomenon was speculated to be a possible origin of superconductivity. Interestingly, the interplay and relationship among CDWs, superconductivity, and spin density waves is still a field of study (Gabovich et al., 2002).

If the translational invariance of ϕ is disrupted, there is a phase for which the CDW energy is the

lowest, and there is also a minimum threshold field to overcome this energy reduction and to initiate the conduction. A possible cause of the invariance break could be that the CDW is commensurate with the lattice. Although this case is unusual and mostly of theoretical interest, such a CDW (with a period quasimultiple of the lattice constant) may contain solitons in the form of constant phase zones, separated by abrupt change areas. This soliton behavior is modeled by sine-Gordon-like equations. However, empirical evidence suggests that the origin of the pinning of the CDW to the lattice and the appearance of a threshold field stem from impurities.

Experimental evidence of CDW behavior became available in the 1970s, and nowadays several materials show CDW behavior, both inorganic, like NbSe_3 , NbS_3 , or $\text{K}_0.3\text{MoO}_3$ ("blue bronze"), and organic, like (fluoranthene) $_2\text{PF}_6$. Evidence of this kind of transition is detected through magnitudes affected by the gap at the Fermi level, including magnetic susceptibility, resistivity, thermoelectric power, scattering experiments where the CDW wave vector manifests itself, and more recently, by means of scanning tunneling microscope images.

Conductivity is among the more interesting properties of CDWs. The dielectric constants for these materials are high, and conductivity suffers an abrupt change from insulating to metallic values of orders of magnitude. The Hall and thermoelectric effects suggest that their conductivity consists of an ohmic linear term and a CDW nonlinear term.

The response of the CDW to a field higher than the threshold value is twofold. First, there appears a high-frequency coherent current, or narrow band noise, which seems to be due to the displacement of the CDW over the pinning potential. Second, a low-frequency broad band noise, incoherent response, is also detected. It is also found that the conductivity saturates for high values of the external field, and it seems that this is due to electrons leaving the CDW region or due to the elimination of $2k_F$ phonons.

When an a.c. field is present, the CDW exhibits a strong dependence on the field frequency, and its conductivity, σ_{ac} , also saturates for high frequencies. There also appear an induced conductivity, σ_{dc} , which increases when V_{ac} increases, and some interference phenomena between the narrow band noise and the a.c. The external field $E_{ac} \cos \omega_e t$ causes oscillations of the current at frequency ω_e , and if there is also a d.c. field, E_{dc} , there are oscillations at frequency ω_i corresponding to the narrow band noise. These two frequencies may interact to produce mode-locking phenomena when they are commensurate ($n\omega_i = m\omega_e$).

In CDW systems, this locking shows up in the step structure of the differential resistance as a function of the d.c. field. As the external d.c. changes, the

nonlinearity of the system keeps the relation between both frequencies constant, ω_i/ω_e , over a finite interval of the external parameter, corresponding to the intervals where dV/dI is constant. When the external parameter moves far from the locking region, the system undergoes a transition to an unlocked state, which is quasi-periodic, with two incommensurate frequencies. The interference between the internal frequency ω_i and the external one ω_e is the origin of the coherent and incoherent responses of the system. Usually, the low-frequency region of the power spectra consists of a broad band noise, while the narrow components show up at high frequencies as narrow band noise. A systematic elimination of the broad band noise when the CDW entered mode locking (Sherwin & Zettl, 1985) and a reinforcement of this noise in the unlocked regime have been observed. The interplay between the internal frequency and the external one may give rise to chaotic behavior, with a period-doubling route to chaos.

Studied in the context of self-organized criticality, CDWs are an example of systems that reorganize themselves near the edge of stability, and any small change in the external electrical field gives rise to a drastic change in the response of the CDW (high increase of conductivity).

Although several models have been proposed to explain CDW behavior, none is completely satisfactory. The classical model considers the CDW as a rigid carrier, without any internal degree of freedom, using the forced oscillator equations with some analogy to the Josephson junctions. The tunneling model focuses on the gap in the excitation spectrum of the CDW, explaining the nonlinear conductivity and the scale relationship between $\sigma_{ac}(\omega)$ and $\sigma_{dc}(E)$. However, these models do not explain the interference phenomena between the narrow band noise and the external field frequency ω .

There are other models that consider the internal degrees of freedom of the CDW (segmenting the CDW either through a hydrodynamical description or the Keldysh-Schrieffer model), but none of them completely explains the phenomenology observed in a CDW. Another interesting model is the Fukuyama-Lee-Rice model, which treats the CDW as a classical extended elastic medium, interacting with impurities and an electric field. Discrete versions of these models have also been used. For the commensurate case, Frenkel-Kontorova and soliton models (such as the sine-Gordon equation) have been used.

Several applications have been suggested for these materials, including tunable condensers, optical detectors, memory devices, and switches, among others.

CHEMICAL KINETICS

Chemical kinetics is a well-defined field of physical chemistry that arose in the 1850s as a complement to the investigation of chemical equilibria. The question of how fast a reactive mixture in a closed vessel reaches equilibrium gave rise to the concept of reaction velocity. The mass action law, enunciated by Cato Guldberg and Peter Waage in 1863, provided a quantitative expression of the velocity of an elementary reaction step in a homogeneous medium in terms of the concentrations or the mole fractions of the reactants involved, and a parameter known as the rate constant. Chemical kinetics is intrinsically nonlinear, since the law of mass action features products of concentrations of the species involved.

Early Developments

Evidence that chemical reactions can generate complex behavior was reported in the early days of chemical kinetics (Pacault & Perraud, 1997). In 1899, Wilhelm Ostwald discovered that in a reaction involving chromium in concentrated acid solution, the release of hydrogen gas was periodic. In 1906, Robert Luther observed propagating chemical reaction fronts in connection with the catalytic hydrolysis of alkyl sulfates. These studies remained isolated for a long time. Possible origins, including the systematic study of reaction mechanisms, were hardly touched upon and there was little or no modeling effort. Not surprisingly, therefore, they came to be regarded by the scientific community as curiosities or even as artifices. On the theoretical side in the 1920s, Alfred Lotka devised a model formally deriving from chemical kinetics and giving rise to sustained oscillations. As the model did not apply to any known chemical system, it was discarded by chemists but was far better received in population dynamics where it played a seminal role. This connection was further enforced in 1926 when Vito Volterra advanced an explanation of ecological cycles

in connection with predator-prey systems, using ideas similar to those of Lotka.

The Phenomenology of Nonlinear Chemical Kinetics

Nonlinear chemical kinetics in its modern form owes much to the Belousov–Zhabotinsky reaction (Zhabotinsky, 1964; Field et al., 1972) dealing with the oxidation of a weak acid by bromate in the presence of a metal ion redox catalyst. In addition to the possibility of displaying long records of oscillatory behavior in batch (closed reactor), this reaction gave rise for the first time to a thorough mechanistic study which highlighted the important role of feedback in the onset of complex behavior, in addition to nonlinearity.

Nonlinear phenomena in chemical kinetics have been observed on whole classes of systems giving rise to a large variety of complex behaviors, as reviewed in a Faraday discussion held in 2001. Quantitative phase diagrams have been constructed separating different behavioral modes as some key parameters are varied (Gray & Scott, 1990; Epstein & Pojman, 1998).

Open Well-Stirred Reactors

Simple periodic, multi-periodic, and chaotic oscillations are observed as the residence time of reactants (inversely proportional to their pumping rate into the reactor) is varied. A second type of phenomenon is multistability, the possibility of exhibiting more than one simultaneously stable steady-state concentration level. A third type of phenomenon is excitability whereby, once perturbed, a system performs an extended excursion resembling a single pulse of an aborted oscillation, before settling back to its stable steady state. Finally, an interesting phenomenology pertains to combustion reactions, where the dependence of the rate constant on temperature is the source of a universal (reaction mechanism-independent) positive feedback.

Open Unstirred Reactors

In the absence of stirring, chemical dynamics coexists with transport phenomena. This can give rise to the generic phenomenon of propagating wave fronts. In a bistable system, a typical front may join the two stable states, with one of them progressing at the expense of the other. In two- and three-dimensional reactors undergoing excitable or oscillatory dynamics, the fronts can take the more spectacular form of circles (target patterns), rotating spirals, and scrolls. An exciting form of spatial self-organization is spontaneous symmetry-breaking leading to sustained steady-state patterns, anticipated by Alan Turing in 1952 and realized experimentally by Patrick De Kepper and coworkers; see Figure 1 (Turing, 1952; De Kepper et al., 2000).

Figure 1. Stationary concentration patterns arising in the chlorite–iodide–malonic acid reaction beyond a symmetry-breaking instability (courtesy of P. De Kepper).

Heterogeneous Systems

Since the late 1980s, a series of novel developments has been initiated following the encounter of nonlinear chemical kinetics with surface science as it is manifested, for instance, in heterogeneous catalysis. Complex behavior in all the above-mentioned forms is observed. Furthermore, the development of sophisticated monitoring techniques, such as field ion microscopy, opens the perspective of monitoring chemical dynamics at the nanoscale level (Hildebrand et al., 1999).

Theoretical Developments: Dynamical Systems and Nonlinear Chemical Kinetics

The essence of nonlinear chemical kinetics is captured by the reaction-diffusion equations (Nicolis & Prigogine, 1977)

$$\frac{\partial c_i}{\partial t} = v_i(\{c_j\}, k_\alpha, \Delta H_\alpha, \dots) + D_i \nabla^2 c_i, \quad (1)$$

where c_i ($i = 1, \dots, n$) denotes the concentrations or the temperature, k_α and ΔH_α the rate constants and heats of reaction of the steps involved, and D_i the mass or heat diffusivity coefficients. The rate function v_i accounts for the nonlinearities and feedbacks, whereas the contribution of transport processes is linear.

The reaction-diffusion equations (1) exhibit nonlinearity in its simplest expression, as a property arising from intrinsic and local cooperative events. Because of this, complex behavior may arise in the absence of spatial degrees of freedom and persist even when few variables are present. In thermodynamic language, reactions are purely dissipative processes, whereas in nonlinear mechanics, inertia plays a very important role in the onset of complex behavior. Understanding how purely dissipative systems can come to terms with the restrictions imposed by the laws of thermodynamics and statistical mechanics has stimulated several fundamental developments (Glansdorff & Prigogine, 1971; Nicolis & Prigogine, 1977). It has also led to the design of canonical models, such as the Brusselator, that are being used with success to test ideas and to assess the limits of validity of approximations.

The intrinsic parameters k and D in Equations (1) has dimensions of $[\text{time}]^{-1}$ and $[(\text{length})^2/\text{time}]$, respectively. It follows that a reaction-diffusion system possesses intrinsic time (k^{-1}) and space ($(D/k)^{1/2}$) scales. This places nonlinear kinetics at the forefront for understanding the origin of endogenous rhythmic and patterning phenomena as observed, in particular, in biology and in materials science. In thermodynamic equilibrium, these intrinsic time and length scales remain dormant, owing to detailed balance. Non-equilibrium allows for the excitation and eventual stabilization of finite amplitude disturbances bearing these characteristic scales.

Equations (1) form the basis of interpretation of the experiments surveyed above. They also constitute some of the earliest and most widely used models of bifurcation and chaos theories. The classical tools used in their analysis are stability theory and the reduction to normal form (amplitude) equations using perturbation techniques and/or symmetry arguments, complemented by interactive numerical simulations (Nicolis, 1995). A most interesting development is the prediction of an impressive variety of intrinsically generated spatial and spatiotemporal patterns, including spatiotemporal chaos, when two or more mechanisms of instability are interfering.

Nonlinear Chemical Kinetics in the Life Sciences

Research in nonlinear chemical kinetics has led to a semi-quantitative interpretation of a wide spectrum of dynamical behaviors in biochemistry (Goldbeter, 1996). This has been possible thanks to the development of models in which the involvement of cooperative enzymes in some key steps provides the principal source of nonlinearity and feedback. Glycolytic oscillations, calcium oscillations and waves, the cell division cycle, cAMP-induced aggregation in amoebae, and synchronization in cell populations are among the main achievements of this effort that helped to identify the principal mechanisms behind the observed behavior.

Nonlinear kinetics has also been a source of inspiration for approaching dynamical phenomena of crucial importance in biology, in which modeling involving a few variables and/or well-established molecular mechanisms is still not available. Immune response, the electrical activity of the brain, embryonic development, cooperative processes such as food recruitment or building activity in social insects, and, last but not least, chemical and biochemical evolution itself (Eigen & Schuster, 1979; *See Biological evolution*) have been explored in one way or the other in the light of the concepts and techniques of nonlinear kinetics.

As a closing remark, Equations (1) anticipate a decoupling between the evolution laws of the

macroscopic observables and dynamics at the microscopic level, which may actually break down when reactive systems are embedded on low-dimensional supports owing to the generation of anomalous inhomogeneous fluctuations. This leads to interesting synergies among nonlinear chemical kinetics, statistical mechanics, and computational science (Nicolis, 2001).

CHERENKOV RADIATION

Cherenkov radiation is the electromagnetic radiation of a charged particle moving uniformly in a medium with a velocity exceeding the velocity of light (c) in that medium. It was discovered experimentally

by Pavel Cherenkov in 1934 and was theoretically explained by Igor Tamm and Il'ja Frank in 1937. (In 1958, Cherenkov, Tamm, and Frank were awarded a Nobel Prize in physics for this work.) Earlier, Cherenkov radiation was theoretically predicted by Arnol'd Sommerfeld, who, in 1904, solved a formal problem on the radiation of a charged particle moving in vacuum with a velocity $v > c$, and by Oliver Heaviside (Heaviside, 1950) at the end of the 19th century.

At present, all radiation phenomena of waves of any origin, created by a source that moves with a velocity exceeding the phase velocity of the waves, are regarded as Cherenkov radiation. Common examples that can be observed in ordinary life include waves created on a water surface by moving objects, the so-called bow waves according to a theory developed by Lord Kelvin (William Thomson) in the middle of the 19th century, and acoustic shock waves brought about in the atmosphere by a supersonic jet or a rocket, first described by Ernst Mach in 1877.

Essentially, Cherenkov radiation can be understood from the following simple considerations. A source moving steadily with a velocity v and depending on coordinates and time as $f(\mathbf{r} - \mathbf{v}t)$ can be presented in the form of a Fourier integral $f(\mathbf{r}, t) = \int f(\mathbf{k})e^{i\mathbf{k}\cdot\mathbf{r} - i\mathbf{k}\cdot\mathbf{v}t}d^3k$, which suggests that each Fourier harmonic has frequency $\mathbf{k}\cdot\mathbf{v}$. In electrodynamics, the role of the source is played by the distribution of charge density $\rho(\mathbf{r} - \mathbf{v}t)$ and current $\mathbf{j} = \rho\mathbf{v}(\mathbf{r} - \mathbf{v}t)$, and in hydrodynamics by external forces and moving particles.

If a source is to excite the waves in a medium whose wave vector $\mathbf{k}$ and frequency ω are related by the dispersion equation $\omega = \omega(\mathbf{k})$, a resonance condition must be satisfied, under which the wave frequency $\omega(\mathbf{k})$ coincides with the external force frequency $\mathbf{k}\cdot\mathbf{v}$. This equality yields the Cherenkov condition

$$\omega(\mathbf{k}) = \mathbf{k} \cdot \mathbf{v}, \quad (1)$$

Figure 1. Wave front configuration by Cherenkov radiation, v is the particle velocity, and k is the wave vector of the emitted wave.

which can be fulfilled only if the moving source velocity exceeds the phase velocity of the waves $v > v_{ph} = \omega(\mathbf{k})/k$.

The radiated wave vectors form a characteristic Cherenkov cone, which is similar to the Mach cone in hydrodynamics. Thus, the angle θ between the wave vector of the radiated wave and the direction of particle velocity is determined by the Cherenkov condition of Equation (1), which requires $\cos \theta = v_{ph}/v$, showing that the frequency distributions of radiation are related to each other. Figure 1 shows the wave front configuration of a wave of frequency ω , emitted by a moving source.

Nowadays, Cherenkov radiation is used in high-energy physics as an important experimental tool (the Cherenkov counter), enabling identification and velocity measurements of fast charged particles, and in electronics for Cherenkov electron oscillators and amplifiers of electromagnetic waves, such as traveling-wave tubes and backward-wave oscillators. Many diverse phenomena can be related to manifestations of Cherenkov radiation, including Landau damping and instabilities in plasma physics, and the Kelvin-Helmholtz instability in hydrodynamics (excitation of waves on a water surface by wind).

CHUA'S CIRCUIT

Having witnessed futile attempts at producing chaos in an electrical analog of the Lorenz equations while on a visit to Japan in 1983, Leon Chua was prompted to develop a chaotic electronic circuit. He realized that chaos could be produced in a piecewise-linear circuit if it possessed at least two unstable equilibrium points—one to provide stretching and the other to fold the tra-

Figure 1. Chua's circuit consists of a linear inductor L , two linear capacitors (C_1 and C_2), a linear resistor R , and a voltage-controlled nonlinear resistor N_R (called a Chua diode).

Figure 2. The V - I characteristic of the Chua diode N_R has breakpoints at $\pm E$ and slopes G_a and G_b in the inner and outer regions, respectively.

jectories. With this insight and using nonlinear circuit theory (Chua et al., 1987), he systematically identified those third-order piecewise-linear circuits containing a single voltage-controlled nonlinear resistor that could produce chaos. Specifying that the V - I characteristic of the nonlinear resistor N_R should be chosen to yield at least two unstable equilibrium points, he invented the circuit shown in Figure 1.

This circuit is described by three ordinary differential equations

$$\begin{aligned} C_1 \frac{dV_1}{dt} &= -GV_1 - f(V_1) + GV_2, \\ C_2 \frac{dV_2}{dt} &= GV_1 - GV_2 + I_3, \\ L \frac{dI_3}{dt} &= -V_2, \end{aligned} \quad (1)$$

where $G = 1/R$. Also, $f(\cdot)$ is the V - I characteristic of the nonlinear resistor N_R (known as a Chua diode), which has a piecewise-linear V - I characteristic defined by

$$f(V_R) = G_b V_R + \frac{1}{2}(G_a - G_b)(|V_R + E| - |V_R - E|), \quad (2)$$

where $\pm E$ are the breakpoints in the characteristic, and G_a and G_b are the slopes in the inner and outer regions, respectively, as shown in Figure 2.

If the values of the circuit parameters are chosen such that the circuit contains three equilibrium points (two in the outer regions and one at the origin), all of which are unstable with saddle-focus stability, then a homoclinic trajectory can be formed, potentially producing chaos.

Soon after its conception, the rich dynamical behavior of Chua's circuit was confirmed by computer simulation and experiment and in 1986 was proven to exhibit chaos in the sense of Shilnikov (Chua et al., 1986). An intensive effort since then to understand every aspect of the dynamics of this circuit has resulted in its widespread acceptance as a powerful paradigm for learning, understanding, and teaching about nonlinear dynamics and chaos (Madan, 1993; Chua, 1992).

By adding a linear resistor R_0 in series with the inductor, Chua's circuit has been generalized to the Chua oscillator (Chua, 1993), with the last of Equations (1) changing to

$$L \frac{dI_3}{dt} = -V_2 - R_0 I_3. \tag{3}$$

Chua's oscillator is canonical in the sense that it is equivalent (topologically conjugate) to a 13-parameter family of three-dimensional ordinary differential equations with odd-symmetric piecewise-linear vector fields. The circuit can exhibit every dynamical behavior known to be possible in a system described by a continuous odd-symmetric three-region piecewise-linear vector field. Unlike the Lorenz or Rössler equations, which have more complex multiplicative nonlinearities, the only nonlinearity in Chua's circuit is a scalar function of one variable. With an appropriate choice of parameters, the circuit can be made to follow the classic period-doubling, intermittency, and torus breakdown routes to chaos; in addition, over 60 different types of strange attractors have been reported in Chua's oscillator.

Figure 3. Robust practical implementation of Chua's circuit/oscillator using two op amps and six resistors to realize the Chua diode. In the case of Chua's circuit, R_0 is zero; in Chua's oscillator, R_0 may assume negative or positive values. Component values for Chua's circuit are listed in Table 1.

Chua's circuit oscillator can be realized in a variety of ways by using standard or custom-made electronic components. Since all of the linear elements (capacitors, resistors, and inductor) are readily available as two-terminal devices, only the nonlinear diode must be synthesized using a combination of standard electronic components. The most robust practical realization of Chua's circuit/oscillator, shown in Figure 3, uses two operational amplifiers (op-amps) and six resistors to implement the nonlinear diode (Kennedy, 1992).

The op-amp subcircuit consisting of A_1 , A_2 , and R_1 through R_6 functions as a Chua diode with $V-I$

Figure 4. Typical experimental bifurcation sequence in Chua's circuit (component values as in Table 1) recorded using a Hitachi VC-6025 Digital Storage Oscilloscope. Table 1. Component list for Chua's circuit.

characteristic as shown in Figure 2. Using two 9 V power supplies for the analog devices AD712, op-amps set their saturation voltages at approximately ± 8.3 V, yielding breakpoints $E \approx 1$ V. With $R_2 = R_3$ and $R_5 = R_6$, the V - I characteristic of the Chua diode is defined by $G_a = -1/R_1 - 1/R_4 = -25/33$ mS and $G_b = 1/R_3 - 1/R_4 = -9/22$ mS. Note that the value of the resistance R_0 is ideally zero in Chua's circuit. In practice, the real inductor L has a small parasitic resistance that can be modeled by R_0 ; the TOKO-type 10RB inductor is preferred because it has a sufficiently low parasitic resistance R_0 for this application.

By reducing the value of the variable resistor R from 2000 Ω to zero, with all other components as in Table 1, the circuit exhibits a Hopf bifurcation from dc equilibrium, a sequence of period-doubling bifurcations to a spiral attractor, periodic windows, a double-scroll strange attractor, and a boundary crisis (Kennedy, 1995).

Although the diode characteristic in Equation (2) is piecewise-linear, qualitatively similar behavior is observed when a smooth nonlinearity such as a cubic is used instead. The piecewise-linear nonlinearity is more convenient for circuit realization, while the smooth nonlinearity is more appropriate for bifurcation analysis.

CLEAR AIR TURBULENCE

Description

In 1966, the National Committee for Clear Air Turbulence officially defined *clear air turbulence* (CAT) as "all turbulence in the free atmosphere of interest in aerospace operations that is not in or adjacent to visible convective activity (this includes turbulence found in cirrus clouds not in or adjacent to visible convective activity)." FAA Advisory Circular AC 00-30B (1997) has simplified this somewhat to "turbulence encountered outside of convective clouds." Thus, CAT is considered to mean turbulence in the clear air, not in or near convective clouds, usually at upper levels of the atmosphere (above 6 km).

CAT was first observed by high-flying fighter aircraft in the mid-to-late 1940s. It was expected that turbulence encounters would be rare at high levels due to the lack of clouds at upper levels. However, it was soon discovered that turbulence encounters in clear air were not only frequent but sometimes quite severe. Since then, CAT encounters have become a significant problem for commercial aircraft flying at cruising altitudes (18,000-45,000 ft above the mean sea level). In fact, various reviews of National Transportation Safety Board (NTSB) reports indicate that in the U.S., turbulence encounters account for approximately 65% of all weather-related accidents or incidents for commercial aircraft; probably more than half of these are due to CAT. Although most turbulence encounters are generally just an annoyance to passengers and crew, on average there are about eight commercial aircraft turbulence-related incidents per year that are significant enough to be reported to the NTSB, accounting for 10 serious and 32 minor injuries. Fortunately, fatalities and substantial damage to the aircraft structure are rare but can occur, as shown in Figure 1.

It should be noted that only a certain range of frequencies or wavelengths of turbulent eddies is felt by aircraft as bumpiness. For most commercial aircraft, this wavelength is anywhere from about 10 m to 1 km.

Figure 1. Damage sustained to a DC-8 cargo aircraft in an encounter with CAT on 9 December 1992 at 31,000 ft over the Rocky Mountains near Evergreen, Colorado. Note the loss of left outboard engine and approximately 6 m of the wing. (Photo by Kent Meiries.)

Shorter wavelengths are integrated out over the aircraft structure and longer wavelengths are felt as “waves” and do not generally have vertical accelerations large enough to be felt as “bumps.”

CAT can be measured quantitatively with instrumented research aircraft or remotely by instruments such as clear air radar and lidar, but by far the majority of measurements are through pilot reports (PIREPs) of turbulent encounters. PIREPs usually report turbulence on intensity scales of smooth, light, moderate, severe, or extreme. Although definitions of these categories are provided in terms of normal accelerations or airspeed fluctuations, there is still an amount of subjectivity associated with these reports. The pilot reporting system is fairly successful in warning other aircraft of turbulence regions encountered, but to use PIREPs to deduce CAT climatology is difficult, since they are biased by air traffic patterns, non-uniform reporting practices, and the tendency to avoid known turbulence areas. One way to reduce these biases is to examine the ratio of moderate or severe PIREPs to total reports in the three-dimensional airspace averaged over many years of reports. This has been done over the continental U.S. (Sharman et al., 2002). The distribution of this ratio of moderate or greater (MOG) severity PIREPs to total PIREPs by altitude for both CAT and in-cloud encounters is shown in Figure 2. Note that above about 8 km, the majority of reports are in clear air. Similar analyses show the occurrence of CAT to be about twice as frequent in winter as in summer. CAT encounters also tend to be more frequent and more severe over mountainous regions, for example, the Colorado Rockies.

One characteristic of CAT is its patchiness in both time and space. These patches tend to be relatively thin compared with their length (the median thickness is about 500 m, whereas the median horizontal dimension is about 50 km); the median duration is about 6 hours (Vinnichenko et al., 1980). Within a patch, the turbulence may be continuous or may occur in discrete bursts that may be very severe but very narrow (1–2 km).

Figure 2. Vertical distribution of the fraction of moderate or greater-intensity (MOG) turbulence pilot reports taken over a two-year period. Solid lines indicate reports in clear air, and dashed lines indicate reports in cloud.

Relation to Kelvin–Helmholtz Instability

From Figure 2, it can be seen that the altitude of maximum occurrence of CAT is at upper levels near the tropopause and jet stream levels. This relation has been known since the 1950s. For example, Bannon (1952) noted that severe CAT tended to occur above and below the jet stream core on the low-pressure side. These areas tend to have large values of the vertical shear of the horizontal wind, and this led to the hypothesis (e.g., Dutton & Panofsky, 1970) that, at least in some cases, CAT may be related to Kelvin–Helmholtz (KH) instability (KHI, *See Kelvin–Helmholtz instability*). The KHI process occurs in stably stratified shear flows when dynamic instabilities due to wind shear exceed the restoring forces due to stability. KH waves (also known as “billows”) are, in fact, commonly observed in the atmosphere near the top of clouds, where the KH distortions become visible (Figure 3).

Further, the KHI connection to CAT has been verified on occasion by simultaneous measurements of KH billows by high-powered radar and aircraft measurements of turbulence (Browning et al., 1970). Although the figure shows a KH wave train at an instant in time, the KHI process is an evolutionary one, where waves develop, amplify, roll up, and break down into turbulent patches. The resultant turbulent mixing will eventually destroy the wave structure and mix out the shear, and density distributions that created it, but if larger scale processes continue to reinforce the shears, the entire process may reinitiate.

The names associated with KHI derive from the early works of Hermann von Helmholtz (1868), who realized the destabilizing effects of shear, and later of Lord Kelvin (William Thomson) (1871), who posed and solved the instability problem mathematically. Richardson (1920), using simple energy considerations, deduced that a sufficient condition for

Figure 3. An example of Kelvin-Helmholtz billows observed in the presence of clouds. © 2003 University Corporation for Atmospheric Research.

stability of disturbances in shear flow occurs when the restoring force of stability (as measured by the buoyancy frequency N) is greater than the destabilizing force of the mean horizontal velocity shear (dU/dz) in the vertical (z) direction. Thus, when the ratio $N^2/(dU/dz)^2$ is greater than unity, the flow should be stable. In honor of Richardson's insight, it has become common to refer to this ratio as the Richardson number (Ri). The linear problem for various stratified shear flow configurations is well reviewed in the texts by Chandrasekhar (1961, Chapter 11) and by Drazin and Reid (1981). The sufficient condition for stability to linear two-dimensional disturbances is that $Ri > 0.25$; $Ri < 0.25$ is necessary but not sufficient for instability. More recently, Abarbanel et al. (1984), using the method of Arnold, were able to show that the necessary and sufficient condition for Liapunov stability to three-dimensional nonlinear disturbances is $Ri > \text{unity}$, in agreement with Richardson's deduction.

Through these theoretical studies, laboratory experiments (e.g., Thorpe, 1987), and more recently, very high-resolution numerical simulations (e.g., Werne & Fritts, 1999), considerable progress has been made in understanding the intricacies of KHI. One (probably common) method in which KHI is initiated in the atmosphere is through longer wavelength gravity-wave-induced perturbations that lead to local reductions (e.g., in the crest of the wave) in Ri to a value small enough to initiate instability. Gravity waves are ubiquitous in the atmosphere and can be generated in a variety of ways, for example, by flow over mountains or by strong updrafts and downdrafts in convective storms. However, the processes by which KHI may lead to turbulent breakdowns within three-dimensional transient gravity waves is not yet completely understood. It should be mentioned that gravity wave breakdown into turbulent patches may also occur through other mechanisms besides KHI. Examples include convective overturning in large-amplitude waves or nonlinear wave-wave interactions (see the reviews by Wurtele et al. (1996) and Staquet & Sommeria (2002) for discussions of some

of these effects). Further, other instability mechanisms besides KHI may lead to CAT, for example, inertial instability or critical-level instability. Thus, the processes by which CAT may be generated at any given time and place are complex, involving many different sources, making its forecasting quite difficult.

One new promising avenue of research is the use of high-resolution numerical simulations of the atmosphere to reconstruct the atmospheric processes that led to particularly severe encounters of CAT (e.g., Clark et al., 2000; Lane et al., 2003). These types of studies have only recently become possible with advances in computing capabilities that allow model runs to contain both the large-scale processes that create conditions conducive to turbulence and the smaller scales that may affect aircraft. Further studies such as these, along with continued theoretical and numerical studies and field measurement campaigns, should lead to a better understanding of CAT genesis and evolution processes.

Until this understanding is available, forecasting of CAT must be accomplished by empirical means. This is done by forecasting various large-scale atmospheric conditions that are known through experience to be related to CAT. Until recently, these diagnostics for likely regions of turbulence had to be performed by laborious weather map analyses of jet streams and upper-level fronts. Nowadays, these diagnostics can be computed from the output of routine numerical weather prediction forecast models. However, the reliability of these turbulence diagnostics is highly variable, and at the moment it seems that better success may be achieved by combining the various diagnostics within an artificial intelligence framework (Tebaldi et al., 2002).

CLUSTER COAGULATION

In 1916, nine years before he was awarded the Nobel prize for his studies of colloidal solutions, the Austro-Hungarian chemist Richard Zsigmondy (1865–1929) brought forth the first model for cluster coagulation. Interpreting the behavior of aqueous solutions of gold colloidal particles, he posited that each cluster of particles is surrounded by a sphere of influence. According to this model, clusters execute independent Brownian motions when their spheres of influence do not overlap. Whenever the spheres of influence of a pair of clusters touch, the clusters instantaneously stick together to form a new cluster. This kind of non-equilibrium kinetics (*See Nonequilibrium statistical mechanics*) has proven to be truly ubiquitous: bond formation between polymerization sites; the coalescence of rain drops, smog, smoke, and dust; the aggregation of bacteria into colonies; the formation of planetesimals from sub-micron sized grains; the coalescence arising in genetic trees; and even the merging of banks to form ever-larger financial institutions are all examples of cluster coagulation.

Cluster coagulation results in a broad distribution of cluster sizes described by $\{n_i(t)\}_{i=1,\dots,\infty}$, where $n_i(t)$

is the number of clusters of size i present in the system at time t . The size of a cluster is defined as the number of unit clusters that it comprises. The primary goal of coagulation theory is to determine the evolution of $n_i(t)$ for all i .

The most important theory of coagulation was given by the Polish physicist Marian Smoluchowski (1872–1917) (Smoluchowski, 1916, 1917). In 1916, prompted by a request from Zsigmondy to provide a mathematical description of coagulation, Smoluchowski postulated that (1) clusters are randomly distributed in space and this feature persists throughout the coagulation process, (2) only collisions between pairs of clusters are significant, and (3) the number of new clusters of size $i + j$, formed per unit time and unit volume due to collisions of clusters of sizes i and j , is proportional to the product of the concentrations $c_i = n_i/V$ and $c_j = n_j/V$:

$$\frac{\text{number of new clusters}}{V \Delta t} = K_{i,j} c_i c_j. \quad (1)$$

Here, V is the volume of the coagulating system and $K_{i,j}$ is the collision frequency factor, also called the *coagulation kernel*.

The rate equation describing the evolution of $c_i(t)$ follows from the balance between the total number of clusters of size i created and annihilated as a result of coagulation:

$$\begin{aligned} \dot{c}_i(t) = & \frac{1}{2} \sum_{j=1}^{i-1} K_{i-j,j} c_{i-j}(t) c_j(t) \\ & - \sum_{j=1}^{\infty} K_{i,j} c_i(t) c_j(t), \quad i = 1, \dots, \infty. \end{aligned} \quad (2)$$

Here, $\dot{c}_i(t)$ is the time derivative of the concentration $c_i(t)$.

This equation—in fact, the chain of nonlinear ordinary differential equations—is called the Smoluchowski coagulation equation (SCE). It describes the evolution of homogeneous aggregating systems with the distribution $c_i(t)$, provided knowledge of $K_{i,j}$ and an initial distribution $c_i(0)$. The SCE does not depend on the spatial dimension in which the coagulation process is taking place. According to modern terminology, Smoluchowski theory is a mean field (*See Phase transitions*) theory of nonequilibrium growth. It neglects fluctuations of the concentrations c_k ; that is, it presumes the existence of the thermodynamic limit: $V \rightarrow \infty, n_k \rightarrow \infty, n_k/V \rightarrow c_k$. For a broad variety of aggregating systems, this proves to be a reasonable assumption. However, the first assumption of Smoluchowski, that correlations in the distribution of the cluster may be disregarded, is not always satisfied. Aggregating systems fulfilling this assumption are called well-mixed. In low-dimensional systems with no “external” mixing mechanism, the cluster

collisions are often not able to provide sufficient mixing. This may result in correlation build-up and, therefore, a breakdown of Equation (2).

The last, essential, albeit obvious, condition for the applicability of the SCE is that interactions between aggregating clusters be treated as instantaneous collisions, that is, $\tau_{\text{col}} \ll \tau_{\text{coag}}$, where τ_{col} is the characteristic time scale of collisions and τ_{coag} is the characteristic time scale of coagulation. Thus, similar to the Boltzmann kinetic equation (See **Nonequilibrium statistical mechanics**), the SCE describes a slow evolution of the distribution due to fast collisions.

For a continuous distribution $c(t, v)$, SCE takes the form of an integro-differential equation (Müller, 1928):

$$\begin{aligned} \partial_t c(t, v) = & \frac{1}{2} \int_0^v K(u, v-u) c(t, u) c(t, v-u) \\ & - c(t, v) du \int_0^\infty K(u, v) c(t, u) du. \end{aligned} \quad (3)$$

Here u, v are the physical sizes of clusters.

Although the SCE establishes a firm foundation for our understanding of a great variety of cluster coagulation processes, other models have also been devised. They include the Oort–van de Hulst–Safonov equation, which describes cluster coagulation as a continuous growth process, and various stochastic models, such as Kingman’s coalescent and the Marcus–Lushnikov process. In this article, we limit ourselves to the Smoluchowski coagulation theory.

The mathematical structure of SCE can be traced to the master equation for stochastic processes:

$$\dot{P}_i(t) = \sum_j (w_{i,j} P_j(t) - w_{j,i} P_i(t)). \quad (4)$$

Here, $P_i(t)$ is the probability of finding the system in a state i at time t , and $w_{i,j}$ is the probability of transition from state j to state i per unit time. Under the aforementioned assumptions of Smoluchowski theory, $P_i = c_i$, $w_{i,j} = K_{i,j} P_i$. Thus, we arrive at the probabilistic interpretation of $K_{i,j}$ as the probability of coagulation of a pair of clusters i and j in unit volume per unit time.

Calculating the coagulation kernel for a particular coagulation mechanism is a separate problem that is beyond the scope of this article. However, a few remarks are appropriate. First, due to the aforementioned time-scale separation, calculation of K can be treated as a stationary problem. Second, the probability of cluster collisions will depend on the cluster geometry. Very often, the aggregates prove to be fractals (See **Fractals; Pattern formation**) having no characteristic size. The coagulation kernel K will then depend on their fractal dimension D_f . Third, the probability of coagulation of a pair of clusters is a product of the probability of their collision and the sticking efficiency E . The latter is defined as the probability of clusters merging once

they have collided. Two practically important limiting cases are distinguished for coagulation of diffusing clusters: diffusion-limited cluster-cluster aggregation (DLCA), when $E \approx 1$, and reaction-limited cluster-cluster aggregation (RLCA), when $E \ll 1$. DLCA and RLCA produce aggregates of different fractal dimensions and have kinetics of different speeds. Fourth, when the coagulation mechanism is scale-free and the aggregates are fractals, the coagulation kernel K should also be scale-free. In mathematical terms this amounts to the following requirement on the function $K(u, v)$:

$$K(\lambda u, \lambda v) = \lambda^\alpha K(u, v) \quad (5)$$

for any real $\lambda > 0$. Such kernels are called homogeneous, and α is called the homogeneity index. Several examples of widely used kernels are listed in Table 1.

Our present knowledge of when solutions of (2) exist and are unique is limited, as the nonlinearity of SCE presents challenging problems for rigorous mathematical analysis. Existence and uniqueness of solutions for all times have been proven for the kernels $K(u, v) \leq C(u+v)$, where C is a constant. This result has recently been extended to the kernels $K(u, v) \leq r(u)r(v)$, where $r(v) = o(v)$, as $v \rightarrow \infty$ (Norris, 1999; Leyvraz, 2003).

The distribution function is significant because any macroscopic property characterizing a given coagulating system can be calculated in the continuous (discrete) case as an integral (sum) over the distribution. From a mathematical point of view, the distribution function is simply a time-dependent measure on the set of all cluster sizes. Therefore, it is natural to look for *weak solutions* to SCE. Weak solutions can be conveniently defined in the continuous case by means of a Laplace transformed SCE, which describes the time evolution of the Laplace transformation of the concentration.

Weak solutions are inverse Laplace transforms of the solutions to this equation. The discrete case can be treated analogously with the help of generating functions. In fact, most of the presently known exact solutions of SCE were obtained by this approach.

Since the total mass of clusters is, apparently, conserved during collisions, the SCE is expected to conserve the first moment of the distribution

$$M_1(t) = \int_0^\infty v c(t, v) dv. \quad (6)$$

It appears as a deceptively simple exercise to prove this by substituting (6) into SCE. The proof, however, hinges on the condition that the infinite sums involved are convergent. Violation of this condition gives rise to the important phenomenon of *gelation*, also known as

Coagulation mechanism	Kernel	Originator (year)
“Mating”	2	Smoluchowski (1916)
Brownian motion	$\frac{(r(u)+r(v))^2}{r(u)r(v)}$; $r(v) \propto v^{1/D_f}$	Smoluchowski (1916)
Isotropic turbulent shear	$(r(u) + r(v))^3$; $r(v) \propto v^{1/D_f}$	Saffman and Turner (1956)
Gravitational coalescence	$(r(u) + r(v))^2 r(u)^2 - r(v)^2 $; $r(v) \propto v^{1/D_f}$	Findheisen (1939)
Polymerization (RA_∞ model)	uv	Flory (1953)
Polymerization (ARB_∞ model)	$u + v$	

Table 1. Examples of kernels. All kernels are given up to a non-dimensional prefactor. D_f is the fractal dimension of the coagulates.

the gel-sol transition or runaway growth. It was first predicted for the kernel $K(u, v) = uv$, which serves as a model of polymerization (See **Polymerization**) in which new links are formed randomly between polymerization sites. In the mean field approximation, this model also describes random graph growth and bond percolation (See **Percolation theory**). An exact solution of this problem shows that starting with monodisperse initial conditions, the first moment $M_1(t)$ begins to decay after a finite time, t_c , whereas the second moment $M_2(t)$, measuring the average cluster size, diverges. This behavior corresponds to the formation of an infinite cluster, or gel, in a finite time due to the coagulation kinetics “accelerating” with growing cluster sizes. The sol mass M_1 decreases, as part of it is being lost to the gel. This kind of kinetics has also proved to be a key to the explanation of the rapid growth of Jupiter and planetesimal growth in the terrestrial planets.

It has been shown that $M_1(t) = M_1(0)$ for all times; that is, the system is nongelling, when $K(u, v) \leq C(u + v)$. A wealth of data suggests that this is, in fact, the exact bound separating gelation at finite times from nongelling behavior, although a rigorous proof has not yet been given.

The nonlinear character of SCE complicates mathematical analysis for arbitrary kernels, and the set of exactly solvable kernels is limited. Considerable progress in understanding coagulation kinetics has been achieved for the wide class of homogeneous (or asymptotically homogeneous) kernels by looking for similarity solutions. This can be done in two different ways, which we shall refer to as the self-preservation theory and the self-similarity theory.

The first approach embodies the notion of a single characteristic size in the system, which can be chosen to be equal to an average cluster size, $s(t)$. The asymptotic solution of SCE is then expected to have a self-

preserving (scaling) form:

$$c(t, v) = s(t)^{-2} \Phi(v/s(t)). \tag{7}$$

The self-preserving form has been further studied with the objective of identifying when it will lead to a power-law distribution asymptotically (Leyvraz, 2003). This approach allows one to obtain sensible results for a large variety of problems, including some extensions of SCE, in an almost automatic manner. However, since the scaling hypothesis is postulated, one cannot estimate a priori the accuracy of these solutions. Experimental data on coagulation often display a power-law distribution over some range of cluster sizes.

The second approach deals with a coagulating system maintained at steady state by an external source of monomers. By analogy with the scaling theories for turbulent flows and the theory of critical phenomena, it may be expected that the steady-state distribution at large sizes will “forget” the forcing scale v_0 and, therefore, will evolve to a scale-free form,

$$c(v) = \text{const} \times v^{-\tau}. \tag{8}$$

A careful mathematical analysis has shown that this is indeed the case for a wide range of homogeneous kernels, and that the asymptotic distribution equals

$$c(v) = \left(\frac{E}{\kappa}\right)^{1/2} v^{-(3+\alpha)/2}. \tag{9}$$

Here, E is the total influx of mass into the system due to the forcing and κ is a kernel-dependent constant.

COHERENCE PHENOMENA

The word *coherence* comes from the Latin *cohaerens*, meaning “being in relation.” Thus, coherence phenomena are those displaying a high level of correlation between several objects.

From the physical point of view, it is necessary to distinguish between two types of coherence: state coherence, which characterizes correlations between static properties of the considered objects, and transition coherence, which describes correlated dynamical processes. These types of coherence are two sides of the same coin, and one obtains a better insight from considering them together.

To gain an intuitive idea of these two types of coherence, imagine a group of soldiers all standing at attention, without moving. This corresponds to state coherence. If the soldiers were all in different positions (some standing, some sitting, some lying down), there would be no state coherence between them. Now, imagine well-aligned rows of soldiers in a parade, moving synchronously with respect to each other. This corresponds to transition coherence. Also, if they were to march with different speeds and in different directions, transition coherence would be absent.

Coherence is related to the existence of a kind of order—be it a static order defining the same positions or an ordered motion of a group. Then, the antonym of *coherence* is *chaos*. Thus, state chaos means the absence of any static order among several objects, and transition chaos implies an absolutely disorganized motion of an ensemble of constituents.

The notion of coherence is implicit in the existence of correlation among several objects (enumerated with the index $i = 1, 2, \dots, N$). Each object, placed in the spatial point $\mathbf{r}_i$, at time t , can be associated with a set $\{Q_\alpha(\mathbf{r}_i, t)\}$ of observable quantities labeled by α . To formalize the definition of state and transition coherence, one may write $Q_i^\alpha = Q_\alpha(\mathbf{r}_i, t)$, where Q_i^α corresponds to a state property of an object, while Q_i^x and Q_i^y describe its motion. As an illustration, assume that Q_i^z are spin components. Another example assumes that Q_i^z is the population difference of a resonant atom, while Q_i^x and Q_i^y are its transition dipoles. Instead of considering the latter separately, it is convenient to introduce the complex combinations $Q_i^\pm \equiv Q_i^x \pm iQ_i^y$. (In general, Q_i^α are not restricted to classical quantities but may be operators.)

If the system is associated with a statistical operator $\hat{\rho}$, then the observable quantities are the statistical averages

$$\langle Q_i^\alpha \rangle \equiv \text{Tr} \hat{\rho} Q_i^\alpha, \quad (1)$$

expressed by means of the trace operation. A convenient way of describing the system features is by introducing dimensionless quantities, normalized to the number of objects N and to the maximal value $Q \equiv \max(Q_i^\alpha)$. Then, one may define the state variable

$$s \equiv \frac{1}{QN} \sum_{i=1}^N \langle Q_i^\alpha \rangle \quad (2)$$

and the transition variable

$$u \equiv \frac{1}{QN} \sum_{i=1}^N \langle Q_i^- \rangle. \quad (3)$$

One may distinguish two opposite cases, when the individual states of all objects are the same and when they are randomly distributed. These two limiting cases give

$$|s| = \begin{cases} 1, & \text{state coherence,} \\ 0, & \text{state chaos.} \end{cases} \quad (4)$$

Next consider the transition characteristic (3) and collective motion of an ensemble of oscillators. Again, there can be two opposite situations, when the oscillation frequencies of all oscillators, as well as their initial phases, are identical and when these take randomly different values. For the corresponding limiting cases of completely synchronized oscillations and of an absolutely random motion, respectively, one has

$$|u| = \begin{cases} 1, & \text{transition coherence,} \\ 0, & \text{transition chaos.} \end{cases} \quad (5)$$

In the intermediate situation, one may say that there is partial state coherence if $0 < |s| < 1$ and partial transition coherence when $0 < |u| < 1$.

Accepting that coherence is not necessarily total, it is convenient to define qualitative characteristics for partial coherence by introducing correlation functions. Let $Q_\alpha^+(\mathbf{r}, t)$ denote the Hermitian conjugation for an operator $Q_\alpha(\mathbf{r}, t)$. When $Q_\alpha(\mathbf{r}, t)$ is a classical function, Hermitian conjugation means complex conjugation. For any two operators from the set $\{Q_\alpha(\mathbf{r}, t)\}$, one may define the correlation function

$$C_{\alpha\beta}(\mathbf{r}_1, t_1, \mathbf{r}_2, t_2) \equiv \langle Q_\alpha^+(\mathbf{r}_1, t_1) Q_\beta(\mathbf{r}_2, t_2) \rangle. \quad (6)$$

The function $C_{\alpha\alpha}(\dots)$ for coinciding operators is called the autocorrelation function. There is also a shifted correlation function

$$B_{\alpha\beta} \equiv \langle Q_\alpha^+ Q_\beta \rangle - \langle Q_\alpha^+ \rangle \langle Q_\beta \rangle,$$

where, for brevity, the spatiotemporal variables are not written explicitly. For describing coherent processes, it is convenient to use the normalized correlation function

$$K_{\alpha\beta} \equiv \frac{\langle Q_\alpha^+ Q_\beta \rangle}{(\langle Q_\alpha^+ Q_\alpha \rangle \langle Q_\beta^+ Q_\beta \rangle)^{1/2}}, \quad (7)$$

which is sometimes termed a "coherence function." Functions (6) and (7) can be specified as second-order correlation functions since, in general, it is possible to define higher-order correlation functions, such as the $2p$ -order function

$$C_{\alpha_1 \dots \alpha_{2p}} \equiv \langle Q_{\alpha_1}^+ \dots Q_{\alpha_p}^+ Q_{\alpha_{p+1}} \dots Q_{\alpha_{2p}} \rangle,$$

which are closely related to reduced density matrices.

Correlations are usually strongest among nearby spatiotemporal points. Thus, function (7) varies in the interval $0 \leq |K_{\alpha\alpha}| \leq 1$, being maximal for the autocorrelation function $|K_{\alpha\alpha}| = 1$ at the coinciding points $\mathbf{r}_1 = \mathbf{r}_2$, $t_1 = t_2$. When either the spatial or temporal distance between two points increases, correlations diminish; this is named *correlation decay*. At an asymptotically large distance, the correlation function (6) for two local observables displays the property of correlation weakening (correlation decoupling)

$$\langle Q_\alpha^+(\mathbf{r}_1, t_1) Q_\beta(\mathbf{r}_2, t_2) \rangle \simeq \langle Q_\alpha^+(\mathbf{r}_1, t_1) \rangle \langle Q_\beta(\mathbf{r}_2, t_2) \rangle, \quad (8)$$

where either $|\mathbf{r}_1 - \mathbf{r}_2| \rightarrow \infty$ or $|t_1 - t_2| \rightarrow \infty$. It is important to stress that property (8) holds only for local observables; thus, for operators representing no observable quantities, correlation decoupling generally has no meaning.

Coherence characteristically implies correlations between similar objects, which require the use of autocorrelation functions. To describe coherence decay, it is also necessary to fix a point from which this decay is measured (usually at $\mathbf{r} = 0$ and $t = 0$), whereupon coherence decay is studied by considering an autocorrelation function

$$C_\alpha(\mathbf{r}, t) \equiv \langle Q_\alpha^+(\mathbf{r}, t) Q_\alpha(0, 0) \rangle. \quad (9)$$

In many cases, there exists a spatial direction of particular importance, for example, the direction of field propagation. It is natural to associate this special direction with the longitudinal z -axis and the transverse direction with the radial variable $r_\perp$. The characteristic scale of coherence decay in the longitudinal direction is called coherence length l_{coh} , where

$$l_{\text{coh}}^2 \equiv \frac{\int z^2 |C_\alpha(\mathbf{r}, t)|^2 d\mathbf{r}}{\int |C_\alpha(\mathbf{r}, t)|^2 d\mathbf{r}}, \quad (10)$$

and the integration is over the entire space volume. Coherence decay in the transverse direction is classified as transverse coherence radius r_{coh} , where

$$r_{\text{coh}}^2 \equiv \frac{\int r_\perp^2 |C_\alpha(\mathbf{r}, t)|^2 d\mathbf{r}}{\int |C_\alpha(\mathbf{r}, t)|^2 d\mathbf{r}}. \quad (11)$$

For isotropic systems, one replaces $r_\perp$ by the spherical radius r and obtains a coherence radius from equation (11). It is natural to call $A_{\text{coh}} \equiv \pi r_{\text{coh}}^2$ the coherence area and $V_{\text{coh}} \equiv A_{\text{coh}} l_{\text{coh}}$ the coherence volume. The typical scale of temporal correlation decay is termed the coherence time t_{coh} , where

$$t_{\text{coh}}^2 \equiv \frac{\int_0^\infty t^2 |C_\alpha(\mathbf{r}, t)|^2 dt}{\int_0^\infty |C_\alpha(\mathbf{r}, t)|^2 dt}. \quad (12)$$

As seen, the coherence length (10) and coherence radius (11) are related to a fixed moment of time, while the

coherence time (12) defines the temporal coherence decay at a given spatial point. Equations (10)–(12) all have to do with a particular coherence phenomenon characterized by the correlation function (9).

Phase transitions in equilibrium statistical systems are collective phenomena demonstrating different types of state coherence arising under adiabatically slow variation of thermodynamic or system parameters (temperature, pressure, external fields, and so on). Phase transitions are conventionally specified by means of order parameters, which are defined as statistical averages of operators corresponding to some local observables. The order parameter is assumed to be zero in a disordered phase and nonzero in an ordered phase. For example, the order parameter at Bose–Einstein condensation is the fraction or density of particles in the single-particle ground state. The order parameter for superconducting phase transition is the density of Cooper pairs or the related gap in the excitation spectrum. Superfluidity is characterized by the fraction or density of the superfluid component. For magnetic phase transitions, the order parameter is the average magnetization. Thermodynamic phases can also be classified by order indices.

Let the autocorrelation function (9) be defined for the operator related to an order parameter. Then, for a disordered phase, the coherence length is close to the interparticle distance and the coherence time is roughly the interaction time. But for an ordered phase, the coherence length is comparable with the system size and the coherence time becomes infinite.

Taking account of heterophase fluctuations in the quasiequilibrium picture of phase transitions, there appear mesoscopic coherent structures, with the coherence length being much larger than interparticle distance, but much smaller than the system size. The coherence time of these mesoscopic coherent structures (their lifetime) is much longer than the local equilibrium time, although it may be shorter than the observation time. Such coherent structures are similar to those arising in turbulence.

Electromagnetic coherent radiation by lasers and masers presents a good example of transition coherence. Such radiation processes are accompanied by interference patterns, a phenomenon that is typical of coherent radiation and can be produced by atoms, molecules, nuclei, or other radiating objects. Interference effects caused by light beams are studied in nonlinear optics. But coherent radiation and related interference effects also exist in other ranges of electromagnetic radiation frequencies, including infrared, radio, or gamma regions. Moreover, there exist other types of field radiation, such as acoustic radiation or emission of matter waves formed by Bose-condensed atoms. Registration of interference between a reference beam and that reflected by an object is the basis for

holography, which is the method of recording and reproducing wave fields.

The description of interference involves correlation functions. Let $Q_i(t)$ represent a field at time t , produced by a radiator at a spatial point r_i . The radiation intensity of a single emitter may be defined as

$$I_i(t) \equiv \langle Q_i^+(t) Q_i(t) \rangle, \quad (13)$$

whereupon the radiation intensity for an ensemble of N emitters is

$$I(t) = \sum_{i,j=1}^N \langle Q_i^+(t) Q_j(t) \rangle. \quad (14)$$

Separating the sums with $i = j$ and with $i \neq j$ yields

$$I(t) = \sum_{i=1}^N I_i(t) + \sum_{i \neq j}^N \langle Q_i^+(t) Q_j(t) \rangle, \quad (15)$$

which shows that intensity (14) is not simply a sum of the intensities (13) of individual emitters but also includes the interference part, expressed through the autocorrelation functions of type (9). The first term in equation (15) is the intensity of incoherent radiation, while the second term corresponds to the intensity of coherent radiation.

COLLECTIVE COORDINATES

The soliton equations describe a number of important nonlinear physical phenomena. However, in real life, these phenomena are not precisely modeled by say the sine-Gordon (SG) equation, the nonlinear Schrödinger (NLS) equation, or some of the other pure soliton equations. Corrective and often small terms are added to include, for example, inhomogeneities, dissipation, or energy input. The resulting wave phenomena possess modified solitonic features that can be treated approximately starting with a pure soliton solution and then allow the parameters of the soliton solution to vary slowly with time under the influence of the perturbations instead of being constant. Solution parameters that are chosen to vary with time are called *collective coordinates*. They encompass the influence of the perturbations in the pure soliton equations. The advantage of introducing collective coordinates is to reduce a problem with infinitely many degrees of freedom to a problem with a few degrees of freedom (Kivshar & Malomed, 1989; Sánchez & Bishop, 1998).

To illustrate the use of a collective coordinate approach, we shall investigate the NLS equation with the perturbative term εR

$$iu_t + u_{xx} + 2|u|^2u = \varepsilon R. \quad (1)$$

Here, $u = u(x, t)$, where x is the spatial coordinate and t is time. Subscripts x and t denote partial derivatives

with respect to these variables. The simple single soliton solution of the pure NLS equation ($\varepsilon = 0$) reads

$$u(x, t) = a \operatorname{sech}(a\theta) \exp(i\xi\theta + i\sigma), \quad (2)$$

where $\theta = x - x_0$. This solution possesses four parameters $(a, \xi, x_0, \sigma) = (y_1, y_2, y_3, y_4)$, which we shall choose as collective coordinates. For weak perturbations, $\varepsilon \ll 1$, we shall assume that the collective coordinates depend slowly on time t due to the influence of εR . In addition, the perturbation leads to a radiation field of small amplitude, which is neglected. A variational approach is employed to determine the time evolution of the collective coordinates, but this is not the only method available. In the framework of a variational approach, the collective coordinates are the generalized coordinates. Although perturbations may destroy the Hamiltonian property of the pure soliton equations, dissipative effects and external nonconservative forces can be accounted for in the variation of a Lagrangian function by introducing generalized forces associated with the generalized coordinates. Below, this is done by introducing a generalized force for each collective coordinate as in classical mechanics.

The unperturbed NLS equation (and its complex conjugate) can be derived from the Lagrangian density (Caputo et al., 1995; Scott, 2003);

$$\mathcal{L}(u, u^*, u_t, u_t^*, u_x, u_x^*) = \frac{i}{2}(u^*u_t - u_t^*u) - |u_x|^2 + |u|^4. \quad (3)$$

The total Lagrangian function is

$$L(y_i, \dot{y}_i) = \int_{-\infty}^{\infty} \mathcal{L} dx, \quad (4)$$

where we denote the collective coordinates $y_i(t)$, $i = 1, 2, 3, 4$, and $\dot{y}_i$ is the time derivative of y_i . Together with Equation (1), the variation of total Lagrangian leads to the Euler–Lagrange equations (Caputo et al., 1995; Scott, 2003)

$$\frac{\partial L}{\partial y_i} - \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{y}_i} \right) = \varepsilon \int_{-\infty}^{\infty} R \frac{\partial u^*}{\partial y_i} dx + \text{c.c.}, \quad (5)$$

where c.c. stands for complex conjugate of the preceding term on the right-hand side. The inhomogeneous term on the right-hand side is interpreted as the generalized force associated with the collective coordinate $y_i(t)$, which is a key result as we do not rely on a perturbation with a strict Hamiltonian nature. Another important feature is that the above approach provides as many dynamical equations as we choose collective coordinates; thus it is straightforward to determine the generalized forces associated with each collective coordinate.

To illustrate the method, we calculate the total Lagrangian for the NLS equation using the simple single soliton solution in (2)

$$L = \frac{2}{3}a^3 - 2a\xi^2 + 2a\xi \frac{dx_0}{dt} - 2a \frac{d\sigma}{dt}. \quad (6)$$

Consider the perturbation

$$\varepsilon R = -i\Gamma u + \frac{ig_0 u}{1 + p/p_s}, \quad (7)$$

describing light propagation through an optical fiber amplifier with a loss factor Γ , gain g_0 , and power $p = \int_{-\infty}^{\infty} |u|^2 dx$. The constant p_s is a saturation power level that is characteristic for a given fiber amplifier. From Equation (5), the resulting dynamical equations for the collective coordinates are

$$\frac{da}{dt} = -2\Gamma a + \frac{2g_0 a}{1 + 2a^2/p_s}, \quad (8)$$

$$\frac{d\xi}{dt} = 0, \quad (9)$$

$$\frac{dx_0}{dt} = 2\xi, \quad (10)$$

$$\frac{d\sigma}{dt} = a^2 + \xi^2, \quad (11)$$

which is a drastic simplification compared to the original perturbed NLS problem. As for the sine-Gordon system, one can define a power balance condition by requiring $\dot{a}(t) = 0$, implying an equilibrium amplitude a_∞ given as $a_\infty = \sqrt{(g_0 - \Gamma)p_s/2\Gamma}$.

A number of other strategies have been designed to determine slow time variation of collective coordinates in perturbed soliton solutions. These include slow variation of scattering data of the inverse scattering theory for pure solitons (Kivshar & Malomed, 1989; Lamb, 1980), more direct perturbation approaches (McLaughlin & Scott, 1978), and utilizing Hamiltonian structures in cases where the perturbation leads to Hamiltonian systems (Caputo & Flytzanis, 1991). An important result of perturbations is the formation of trailing radiation fields, which are low-amplitude linear waves created as perturbed solitons propagates (McLaughlin & Scott, 1978; Kivshar & Malomed, 1989; Willis, 1997). The solitons lose energy to the radiation field, and the variational approach used here can be extended to include such radiation.

COLLISIONS

An interesting consequence of Hamiltonian structures is that there typically exist symmetries and invariances that allow one to generate mobile localized states from standing ones. For instance, the sine-Gordon (SG) equation (Dodd et al., 1982)

$$u_{tt} = u_{xx} - \sin(u), \quad (1)$$

where the subscripts denote partial derivatives, is invariant under the Lorentz transformation $x \rightarrow x' = \gamma(x - vt)$ and $t \rightarrow t' = \gamma(t - vx)$, $\gamma = \sqrt{1 - v^2}$. As a result, static kinks and antikinks, corresponding to the two signs of the solution

$$u(x, t) = \pm 4 \tan^{-1}(x - x_0), \quad (2)$$

can be boosted to any subluminal speed $v < 1$, as

$$u(x, t) = \pm 4 \tan^{-1}[\gamma(x - x_0 - vt)]. \quad (3)$$

Similarly, standing waves of the nonlinear Schrödinger (NLS) equation

$$iu_t = -u_{xx} - |u|^2 u \quad (4)$$

can be boosted by Galilean invariance into traveling ones with any speed v of the form (Sulem & Sulem, 1999)

$$u(x, t) = (2\alpha)^{1/2} e^{i(v/2)x + i(\alpha - (v^2/4))t} \times \text{sech}(x - x_0 - vt). \quad (5)$$

Note that localized solutions of dissipative partial differential equations do not typically share such features, because their traveling wave speeds are determined by the dynamics rather than initial conditions. Hereafter, we will focus on Hamiltonian models.

Figure 1. Elastic collisions: (a) linear-shaped antikink and kink in the linear wave equation; (b) kink-kink repulsive collision in SG; (c) antikink-kink attractive collision in SG. Top panels show $u(x, t)$, while bottom panels show the trajectories of soliton cores in the (x, t) -plane. (d) Inelastic collisions between two NLS solitons in the presence of weak perturbation.

Given the mobility of the localized coherent structures, it is natural to consider the outcome of their collisions. In fact, it was the “solitary” nature of such interactions (Zabusky & Kruskal, 1965) that inspired the term *soliton* in the case of integrable systems.

Linear versus Nonlinear Collisions

Consider the collision of two wavepackets that are governed by a linear wave equation. In this case, the superposition principle inherent in linearity guarantees that the two packets do not “feel” each other and survive the collision without change of shape, speed, or trajectory (see Figure 1(a)).

On the other hand, nonlinear dynamics offers more interesting collisions. Here, the result of the interaction of two excitations does not resemble their sum and (at least) a phase shift Δ is present (compare Figures 1(b) and 1(c) with 1(a)). In 1(b) and 1(c), the kink-kink and the antikink-kink collisions in the nonlinear SG equation are shown. The soliton cores do not merge in mutually repulsive collisions 1(b) while they do so in attractive collisions 1(c).

Elastic versus Inelastic Collisions

In fully integrable systems, solitons have the remarkable property (often used to define them) of colliding elastically (Ablowitz & Segur, 1981). In these special systems, the dynamics are severely restricted by the existence of an infinite set of conservation laws. Although realistic systems are typically non-integrable, the non-integrability in many applications is weak and can be treated by including small perturbative terms in integrable equations. Such perturbations are called Hamiltonian if the total energy of the perturbed system

remains a dynamical invariant. While collisions in linear systems are much simpler than those in integrable nonlinear systems (such as the SG and NLS equations), the latter can, in turn, also be very different from the much more complex picture of inelastic collisions in near-integrable or more generally non-integrable systems.

In general non-integrable systems, the inelasticity of collisions may be manifested through emission of radiation, excitation of soliton internal modes, and energy exchange between solitons. Internal modes are the long-lived, spatially localized, oscillatory excitations (corresponding to the point spectrum of the linearization around the wave). These can typically be excited only for a particular sign of the perturbation (Campbell et al., 1983).

Small-amplitude radiation waves correspond to an irreversible chunk of energy lost in the collision (radiated toward the boundaries). Such modes are extended, plane waves of the continuous spectrum. Notice that the energy of internal modes can be partly restored to solitons if they collide again, while this is not possible for radiation waves (in the first-order approximation).

Strong energy exchange between nonlinear waves in near-integrable systems can also occur in the absence of the above two mechanisms (and for different types and signs of the original perturbation). There are two necessary conditions for this recently manifested mechanism (Dmitriev et al., 2001, 2002). It can be observed only if the energy exchange is not forbidden by the conservation laws existing in the perturbed system and if the collision is of attractive type, as in Figure 1(c). For example, in the SG equation perturbed by the term ϵu_{xxxx} , where energy and momentum are conserved for the one (free)-parameter kink-solitons, energy exchange is possible only when more than two solitons participate in the collision. The energy exchange between only kinks or only antikinks is also not possible because SG solitons with the same parity repel each other. Similarly, the effect is not possible in the Korteweg-de Vries (KdV) equation, where soliton interactions are always mutually repulsive.

In the NLS equation, in-phase solitons attract each other, while out-of-phase solitons repel. Each soliton has two parameters (amplitude and phase), and for many practically important perturbations, there are two conserved quantities: the Hamiltonian and L^2 norm of the solution. Thus, energy exchange between two nearly in-phase NLS solitons is possible in the presence of a weak perturbation. The effect of radiationless energy exchange between solitons survives even for a very weak perturbation, as it decreases linearly with a decrease in perturbation amplitude, while other effects of the perturbation decay faster. If the perturbation is not small, the energy exchange effect mingles with

radiation emission and possibly with the excitation of internal modes.

Probabilistic Nature of Soliton Collisions

In many examples of perturbed, non-integrable models related to applications in optics, fluid mechanics, or condensed-matter physics (Kivshar & Malomed, 1989), the result of soliton collisions can be predicted only in a probabilistic sense. The following sources of stochastic behavior can be identified. First, chaotic soliton scattering can arise from resonant interaction with the soliton internal modes (Campbell et al., 1986; Gorshkov et al., 1992). Second, in discrete systems, the result of inelastic collisions can be sensitive to the coordinate of collision point, x_c , with respect to the lattice site (Dmitriev et al., 2003; Papacharalampous et al., 2003). Because the coordinate of the collision point usually cannot be controlled, it is natural to describe the result of the collision as a function of the random variable x_c . Finally, the result of the collision can be extremely sensitive to some other uncontrolled characteristics, such as the relative phase of the colliding solitons, as has been demonstrated to dramatically affect the collisions between NLS solitons or between kinks and breathers in SG (Dmitriev et al., 2001, 2002, 2003; Papacharalampous et al., 2003).

This last source of randomness is important when energy exchange between solitons is possible. In Figure 1(d), an example of inelastic interaction between two NLS solitons in the presence of quintic perturbation, $\varepsilon|u|^4u$ in Equation (4), with a small $\varepsilon > 0$ is presented (Dmitriev & Shigenari, 2002). (The regions of the (x, t) -plane are shown, where the real part of the solution exceeds a certain value.) After each collision, the properties of the solitons such as the frequency and amplitude are different depending on the collision phase. With a certain probability, the solitons can attain (after a number of collisions) a velocity sufficient to overcome their weak mutual attraction. In the example presented, the solitons split after the fourth collision. Emission of extended wave radiation is monitored and found to be very weak in this case; as a result, the solitons may continue to collide for a very long time, forming a two-soliton bound state. However, the probability P to obtain a bound state with the lifetime T decays algebraically as $P \sim T^{-\alpha}$ (Dmitriev & Shigenari, 2002), which is a manifestation of the chaotic character of their interaction.

In conclusion, linear waves do not "feel" each other, and nonlinear waves of integrable equations emerge unscathed from collisions, retaining their solitary character. However, solitary wave collisions in more realistic, non-integrable models remain a fascinating topic, where a number of basic mechanisms (such as internal mode resonances, extended wave

radiation, and radiationless energy exchange) have been elucidated, but the full picture is far from complete. The probabilistic interpretation of collisions mentioned above may prove a fruitful viewpoint in future studies.

COLOR CENTERS

Gemstones are brightly colored because of the presence of *color centers*, atomic-scale imperfections that absorb light in otherwise transparent crystals. Historically, the term *color centers* has been associated with such imperfections in a special class of crystals called alkali halides, because it was in these relatively simple transparent hosts that the scientific study of color centers flourished. A German research program that

began in the 1930s soon led to the recognition that alkali halides are excellent hosts for scientific studies of defects in nonmetallic solids, and the understanding of fundamental properties in these materials has been of great significance in the studies of similar phenomena in more complicated (and sometimes more practical) situations and materials.

Sodium chloride—common table salt—is the most familiar alkali halide. It consists of positively charged sodium and negatively charged chlorine ions, alternating positions in a simple cubic array. In the perfect crystal, each ion has six nearest neighbors of opposite charge. Simple defects may involve chemical impurities, such as a positively charged silver or thallium ion on an alkali site, or the removal of one or more ions from normal positions. The most fundamental of the latter class is the F center (from the German *Farbzentrum*), a halogen ion vacancy that has trapped an electron. Defects involving more than one F center, or chemical impurities next to one or more F centers, may also occur.

Understanding the properties of color centers in detail requires some knowledge of quantum concepts. For example, the trapped electron of an F center can exist only in certain quantum states. In order for light to be absorbed, the energy of an incident photon must match the energy difference between the lowest quantum state and a higher one. This energy difference depends on the host crystal, and so F centers induce different colors in different alkali halides.

The situation becomes more complicated when one considers that the electron is not trapped in a static host, but rather that the neighboring ions are vibrating. The electron's interaction with these vibrations, whose time scale is long with respect to that of the (light) electron's motion, means that the energy difference between ground and excited electronic states does not have a single value, but rather a distribution of values about some mean. Thus, for example, whereas the mean photon absorption energy for F centers at low temperatures in NaCl is 2.77 eV, the mean width of the distribution of absorption energies is 0.26 eV.

This *electron-lattice interaction* has other consequences. In most cases, an F center at low temperature that has been excited by light will re-emit light. However, the mean energy of the emitted photon is found to be considerably smaller than that of the absorbed photon. This *Stokes shift* is exemplified in NaCl, where the mean photon emission energy at low temperatures is 0.98 eV.

Why is there a Stokes shift? In simple terms, the energy-level structure of the F center is determined by the mean position of the neighboring ions. However, the mean position of the neighboring ions is in turn determined by the quantum state of the F center electron. After the electron is excited from the ground state to another quantum state, the neighboring ions relax in

response to the change in the average force exerted on them by the electron. This relaxation then leads to a change in the energy-level separations, as well as other fundamental aspects of their properties. The emitted photon has an energy smaller than the absorbed photon had, and energy is conserved in the total cycle as the relaxation processes create quanta of lattice vibrations, or phonons, which remove the excess energy.

This cyclic process may be visualized by means of a configuration coordinate diagram. In the simplest case, this diagram consists of two equal parabolas, displaced vertically (in energy, E) and horizontally (in the displacement of neighboring ions, R), as shown in Figure 1. Each parabola represents the vibration of neighboring ions and leads to quantized vibrational states. According to the Franck-Condon principle, electronic transitions take place vertically on the diagram—the massive ions do not respond instantly to the excitation by the photon—so absorption corresponds to a transition from A to B, emission C to D. This picture is highly oversimplified, but it does represent a physical and visual way to understand phenomena associated with the optical properties of F centers (and by extension, many other types of defects in both insulators and semiconductors).

We now consider a perfect alkali halide crystal in which one electron has been removed by light (ionizing radiation) from the array of negative ions. At low temperatures, this is found to lead to the phenomenon of self-trapping, whereas in semiconductors, the removal of an electron from a valence band of occupied states leads to motion of the empty state, or hole, and resulting electrical conduction; in most alkali halides the missing charge becomes localized in space, or self-trapped. What happens in detail is that the halogen ion that has lost one electron (and become a neutral atom) can form a chemical bond with a nearby halogen ion. In the process, both of these move toward each other, the lattice around them relaxes, and the missing charge is equally shared by this halogen molecule-ion.

Self-trapping is not a universal process; it “costs” energy to localize a quantum particle, and the energy

Figure 1. Schematic configuration coordinate diagram.

Figure 2. Adjacent F center and self-trapped hole center in an alkali halide. “+” and “-” denote alkali and halogen ions, respectively.

gained by chemical bonding and relaxation must overcome this. Self-trapping of holes occurs in most alkali halides, but not in semiconductors and not in many other insulators. Also of interest is the creation of defects by the self-trapping of excitation energy in alkali halides, leading to a *self-trapped exciton*. To approach this, we consider the trapping of an electron by a self-trapped hole. Since the hole is effectively positive (it resulted from the removal of an electron), we might imagine that the trapped electron would find itself in loosely bound quantum states about the self-trapped hole. However, there is another possibility. If it does not cost too much energy for the halogen molecule-ion to move into one halogen site, rather than be shared by two sites, then the electron may be trapped in the other, empty halogen site. One then has an F center next to a halogen molecule-ion; hence, two defects have been formed. This situation is shown in Figure 2. Since the two defects are adjacent, this may be an unstable arrangement, and indeed there is a finite probability that the system will revert back to the perfect crystal, either before or after the emission of a photon. But, in many cases, it is found that this nearest-neighbor arrangement is the precursor for the creation of a stable defect pair: the halogen molecule-ion may migrate through the halogen sublattice, not by long-range atomic motion, but rather by short-range halogen motion accompanied by motion of the hole. This results in sequential sharing of the hole by the halogens as the hole migrates away from the F center.

COMMENSURATE-INCOMMENSURATE TRANSITION

When some local property in a crystalline solid (atomic positions or orientation of local magnetic moments) develops a spatial modulation with a wavelength b that differs from the underlying lattice spacing a , one speaks of a “modulated phase.” A modulated phase is said to be “commensurate” when the ratio b/a is rational and “incommensurate” when b/a is irrational.

Modulated phases are experimentally observed by the appearance of “satellite spots” in X-ray, neutron, or electron diffraction patterns (Janssen & Janner, 1987; Cummins, 1990). Observations of spatially modulated structures are abundant in condensed matter physical systems, such as the ferrimagnetic phases of the rare earths and their compounds, long-period structures of binary alloys, graphite intercalation compounds, or the polytypic phases of spinelloids, perovskites, and micas, among other minerals.

The wavelength b characterizing the modulation varies with external parameters, such as temperature, pressure, or magnetic field. Sometimes, this variation is smooth, but often it remains constant at a rational locking value through some range of values of the external parameter before changing to another rational locking value, and so on.

The ubiquity of modulated phases shows that the physical origin of these behaviors cannot be tied to particularities of specific types of systems, but must be of a general character. It is widely recognized that modulated phases appear whenever different terms in the free energy of the system compete, each one trying to impose its own characteristic length scale. The external parameters control the relative strength of the competing interactions and new compromises are reached as they vary.

An insight into the physics of modulated phases was obtained through detailed analyses of simple model systems of competing interactions. Although these simple models are unlikely to fit experiments on specific materials, they help to understand the complexity of behaviors that emanate from length-scale competition and to discern essential features.

One of the best-studied model systems with competing interactions is the axial next-nearest-neighbors Ising (ANNNI) model (motivated by the

magnetic structures of erbium), which was introduced by R.J. Elliot in 1961 (Yeomans, 1988). This is an Ising model with a two-state spin, $S = \pm 1$, on each site of a cubic lattice. Interactions between spins on nearest-neighbor sites are ferromagnetic, but there are second (next-nearest) neighbor antiferromagnetic interactions along the axial direction, z . The Hamiltonian is

$$H = -\frac{1}{2}J_0 \sum_{i,j,j'} S_{i,j} S_{i,j'} - J_1 \sum_{i,j} S_{i,j} S_{i+1,j} - J_2 \sum_{i,j} S_{i,j} S_{i+2,j}, \quad (1)$$

where i indicates the two-dimensional layers perpendicular to the axial direction, and j, j' are nearest-neighbor sites within a layer. Both J_0 and J_1 are positive (ferromagnetic interactions), thus favoring the same value of neighboring spins, but $J_2 < 0$ (antiferromagnetic) so that it favors opposite values of second neighbor spins along the z -direction.

In the absence of thermal effects ($T=0$), the favored spin configurations along the z -direction are the ferromagnetic alignment ($\cdots + + + + + \cdots$) if $\kappa = -J_2/J_1 < \frac{1}{2}$, and the antiphase ($\cdots + - - - + \cdots$) configuration if $\kappa > 1/2$. Exactly at $\kappa = \frac{1}{2}$, any configuration containing a stripe of two or more spins “+” followed by a stripe of two or more spins “-”, etc., has the same energy; thus there is a multiphase point.

A convenient notation is to use $\langle n_1, \dots, n_m \rangle$ to represent a state in which a set of stripes of width n_i of alternating spins repeat. For example, $\langle \cdots + - - + + - - + + - - \cdots \rangle$ is denoted by $\langle 223 \rangle$. Ferromagnetic and antiphase configurations are consistently denoted by $\langle \infty \rangle$ and $\langle 2 \rangle$, respectively. When temperature increases from zero, entropic effects regulate the competition among the ferro and antiferro interactions, and a flower (called a “devil’s flower” by Per Bak) of petal-like phases of modulated structures opens up from the multiphase point.

Figure 1 shows how new commensurate phases appear as temperature increases, demonstrating qualitatively what is commonly observed in experiments—locking to a few short-wavelength commensurate phases separated either by first-order phase transitions (as in the low-temperature regime of Figure 1) or by regions where the wave vector appears to vary smoothly (as at higher temperatures).

The following question naturally arises: what determines the behavior of the modulation wave vector as parameters vary? The answer to this question is closely tied to a central paradigm of nonlinear science, the soliton concept in the context of its discrete counterpart called discommensuration.

To clarify this issue, consider the simplest model of competing interactions (Griffiths, 1990), the Frenkel-Kontorova model, which can be visualized as an array of atoms at positions (u_n) , $-\infty < n < +\infty$, experiencing

Figure 1. Mean-field phase diagram of the ANNNI model showing the main commensurate phases.

a periodic substrate potential $V(u) = V(u+1)$ and nearest-neighbor interaction $W(\Delta u)$. The Hamiltonian is

$$H = \sum_n [K V(u_n) + W(\Delta u_n)], \quad (2)$$

where the parameter K controls the relative strength of the interactions. The standard Frenkel-Kontorova model corresponds to

$$V(u) = \frac{1}{(2\pi)^2} [1 - 2 \cos(2\pi u)],$$

$$W(\Delta u) = \frac{1}{2} (\Delta u)^2 - \sigma \Delta u. \quad (3)$$

Note that V favors an integer value of the interspacing Δu , while W favors a uniform value σ , so both interactions compete to determine the configuration (u_n) , characterized here by the average interspacing $\omega = \langle \Delta u \rangle$.

If (as in the standard model) the interaction $W(\Delta u)$ is a convex function, a complete rigorous characterization of the model phase diagram was given by Aubry (1985). Thus, we restrict the analysis to convex $W(\Delta u)$.

In the thermodynamic limit of the system, care must be taken when defining what is meant by configurations of minimum energy or even by the energy of a configuration. Thus, the mean energy ε per particle of a configuration (u_n) is defined as

$$\varepsilon = \lim_{(N-M) \rightarrow \infty} \frac{1}{N-M} \times \sum_{j=M}^{N-1} [K V(u_j) + W(u_{j+1} - u_j)]. \quad (4)$$

A minimum energy configuration (MEC) (u_j) is that for which the arbitrary displacement of any finite segment $(u_j + \delta_j)$, $M < j < N$, of the configuration always produces a nonnegative energy change. For an MEC, both limits (ω and ε) exist. Moreover, for every real number ω , there is at least an MEC with average spacing ω , and its mean energy per particle $\varepsilon(\omega)$ is

a well-defined function. A ground state is an MEC that is “recurrent,” meaning that any arbitrary finite segment of the configuration approximately reappears somewhere else, within arbitrary precision. One often speaks of the ground state that corresponds to fixed values of the parameters (K and σ for the standard model), meaning the ground-state configuration for which $\varepsilon = \min_{\omega} \varepsilon(\omega)$ occurs at the fixed values of the parameters. The minimum ε , which depends on the parameter values, is the ground state energy, and the value of ω where that minimum occurs is the ground-state average spacing.

The ground-state phase diagram of the standard Frenkel–Kontorova model is shown in Figure 2. Some low-order commensurate phases (rational ω) are shown there, but in between any two of them, there are an infinite number of others. The ground-state average spacing ω as a function of the tension σ , for a fixed value of $K=1$, is shown in Figure 3. This is a continuous function with plateaus of (rational) constant value, which correspond to commensurate phases. This function is called “devil’s staircase” or Cantor function. No first-order phase transitions between commensurate phases of different commensurabilities are allowed in convex models.

Figure 2. Ground-state phase diagram of the standard Frenkel–Kontorova model. Each point in the diagram is characterized by the value of ω , average spacing of the groundstate configurations for the parameters (K , σ) of the model. The numbers in the figure are values of ω . Only a few commensurate phases are plotted, as there are infinitely many commensurate and incommensurate phases in between any two of them.

Figure 3. ω as a function of σ at $K=1$, a devil’s staircase, there being a “plateau” for each rational value of ω .

For rational values of $\omega_c = p/q$, commensurate ground states are periodic configurations: $\sigma_{qp}(u_n) := (u_{n+q} - p) = (u_n)$. But there are also two MECs with average spacing (ω_c) that are nonrecurrent and called elementary “discommensurations” (DC). These can be described as a localized compression (retarded DC) or a localized expansion (advanced DC) over a commensurate ground state. The distortion being localized, they have the same mean energy per particle $\varepsilon(\omega_c)$ of the ground state. However, the difference of the non-averaged energy of a DC and the ground state (the extra energy of the localized compression or expansion) is generally nonzero; this is called the “creation energy” of the DC.

If a configuration contains two elementary DCs superimposed on a commensurate ground state, the energy difference with respect to the ground state can be understood as the sum of the creation energies of the DCs plus the interaction energy. If both DCs are of the same type, the energy decreases with the interdistance (repulsive interaction). The interaction is attractive for DCs of opposite type. Elementary DCs have an *excess length* Δ with respect to the ground state, which is exactly $\Delta = 1/q$ for an advanced DC and $\Delta = -1/q$ for a retarded one.

The creation energy of a DC varies linearly with the tension σ , the slope being the excess length Δ of the DC. Inside the corresponding commensurate plateau, the creation energy of an advanced DC increases with σ and disappears at the left edge σ_{c-IC}^- of the plateau, while the creation energy of the retarded DC decreases with σ , disappears at the right edge σ_{c-IC}^+ (see Figure 4). Inside the commensurate plateau, the creation of an elementary DC is energetically costly, but right after either edge (σ_{c-IC}^- or σ_{c-IC}^+) is crossed, it becomes energetically advantageous to create as many DCs (of the correct type) as possible, were it not for the repulsive interaction between them that prevents condensation of an infinite number of DCs.

Figure 4. Creation energy ε_c of both types of elementary discommensurations for values of σ inside the tongue associated with a rational ω . At a certain critical value of σ this energy becomes negative and a commensurate–incommensurate transition occurs, changing the average spacing of the ground-state configuration.

The compromise between these two effects determines the density c of DCs, and, as each DC carries an excess length Δ , the average spacing of the new structure is $\omega = \omega_c + c\Delta$. For very small values of $|\sigma - \sigma_{C-IC}|$, where the interdistance (c^{-1}) is so large as to approximate a continuous variable, the scaling behavior of the ground-state average spacing ω in the commensurate-incommensurate transition is then

$$|\omega - \omega_c| \sim -(\ln |\sigma - \sigma_{C-IC}|)^{-1}. \quad (5)$$

For nonconvex interactions, the basis for an interpretation of the transitions between modulated phases in terms of interacting DCs is less rigorously supported. However, the central idea that the creation of localized defects or discommensurations drives these transitions and that the character (repulsive, attracting, or oscillatory) of their interaction determines the type of transition has been successfully applied, and undoubtedly it provides the most physical way of understanding why and how transitions between modulated phases occur. This fact adds to the many merits of the soliton paradigm in nonlinear science.

COMPARTMENTAL MODELS

Compartmental models, which model the flow of material between components of a system, have been applied to the study of nutrient or energy flow in

an ecosystem, to analyses of tracer kinetics in an organism, and to the theory of epidemics, among other applications.

The construction of a compartmental model is straightforward and intuitive, but the estimation of the associated parameters is not. The system is divided into homogeneous compartments, and the flow of “material” (meaning nutrients, energy, money, goods, electrons, radioactive tracers, information, etc.) between them is traced, keeping account of the level of material in each compartment. The compartments are represented by boxes and the flows are represented by arrows (see Figure 1).

This representation is a directed graph in which the compartments are vertices and the flows are arcs. To analyze a system, however, the model must be quantized by studying the rate of change of the level x_i of the i th compartment in time as

$$x_i = x_i(t). \quad (1)$$

The flow between the i th and j th compartment, designated f_{ij} , is a rate, measured in terms of quantity of material per unit time.

A differential equation describing the behavior of x_i may be obtained by equating the time rate of change of x_i to the difference between the flows coming in and those going out of the i th compartment. Thus,

$$\frac{dx_i}{dt} = \sum_k f_{ki} - \sum_j f_{ij}.$$

rate of change = flows in – flows out

(2)

The f_{ij} may be constant or variable in time and are usually functionally dependent on the x_i ’s.

A widely used assumption (particularly in physiology and medicine) is that

$$f_{ij} = a_{ij}x_i, \quad (3)$$

which corresponds to a certain fraction a_{ij} of the level of material x_i in compartment i passing to compartment j per unit time. In the ecological literature, this is often

Figure 1. A compartmental model of tracer kinetics.

called donor-controlled flow. (The a_{ij} may be functions of time but are usually assumed to be independent of the x_i s.)

Tracer Kinetics

Tracer kinetics refers to a technique for studying the flow of a drug or other material through a biological system (often a human body) near steady state. A small quantity of radioactive isotope or other recognizable form of the material (the tracer) is introduced, so that the tracer flows may be modeled by linear equations.

As a simple example, consider lipoprotein metabolism. One compartment corresponds to the blood plasma and the other corresponds to the extravascular space. A unit dose of tracer is injected into the blood and the flow follows the diagram in Figure 1. The quantity of interest is the flow out of compartment 1 (excretion), which cannot be measured directly, although the level of compartment 1 over time is known.

The differential equations are those obtained from (2) by taking the flow rates to be donor controlled; thus,

$$\begin{aligned} dx_1/dt &= -a_{10}x_1 - a_{12}x_1 + a_{21}x_2, \\ dx_2/dt &= a_{12}x_1 - a_{21}x_2, \end{aligned} \quad (4)$$

with initial conditions

$$x_1(0) = 1, \quad x_2(0) = 0. \quad (5)$$

These equations can be solved for $x_1(t)$ in terms of the three parameters a_{10} , a_{12} , a_{21} ; since x_1 is known for all t , this result can be used to estimate these parameters by fitting a number of nonlinear equations.

General Differential Equations and Solutions

The differential equations for a system of n compartments can be written in vector form as

$$d\mathbf{x}/dt = A\mathbf{x} + \mathbf{f}, \quad (6)$$

where A is the matrix given by

$$A = \begin{bmatrix} a_{11} & a_{21} & \cdots & a_{n1} \\ a_{12} & a_{22} & \cdots & a_{n2} \\ \cdots & \cdots & \cdots & \cdots \\ a_{1n} & a_{2n} & \cdots & a_{nn} \end{bmatrix} \quad (7)$$

and $\mathbf{x} = [x_1, x_2, \dots, x_n]^T$ is the vector of levels of material in the n compartments and $\mathbf{f}$ is the input vector. The a_{ij} for $i \neq j$ are the flow rates, while the diagonal elements of A are

$$a_{ii} = -\sum_{j \neq i} a_{ij} - a_{i0}. \quad (8)$$

Although the input to a compartmental system is often to a single compartment, it may be distributed

to input compartments. In general, we assume that the input to the system is $\mathbf{f} = B\mathbf{u}$, where $\mathbf{u}$ is a vector function distributed to the various compartments by B . Typically, B has one column but as many rows as there are compartments.

The outputs (measurements) of the system may be similarly combined. If the system is assumed donor to be controlled, the output will have the form

$$\mathbf{y} = C\mathbf{x}, \quad (9)$$

where the output of the compartments is directed to one or more measuring devices with measurements $\mathbf{y}(t)$. (Here, C is a general sampling matrix that is usually composed of 0s and 1s.)

The problem is then translated to the differential equation form

$$\begin{aligned} \frac{d\mathbf{x}}{dt} &= A\mathbf{x} + B\mathbf{u}, \\ \mathbf{y} &= C\mathbf{x}, \\ \mathbf{x}(0) &= \mathbf{0}. \end{aligned} \quad (10)$$

where we have assumed that the initial levels are $\mathbf{0}$. (This is no restriction as an initial value can be incorporated into $B\mathbf{u}$.) Solutions of the system are determined by matrices A , B , and C as

$$\mathbf{y}(t) = C\mathbf{x}(t) = C \int_0^t e^{A(t-s)} B\mathbf{u}(s) ds \quad (11)$$

where $\mathbf{x}(0) = \mathbf{0}$. Typically, however, the flow rates in the matrix A are unknown and must be determined from knowledge of $\mathbf{u}(t)$ and $\mathbf{y}(t)$, which is called the identification problem. A system is said to be identifiable if there is a unique solution to this problem, which is not always the case, and even if a solution does exist, it may be difficult to find.

Parameter Estimation

The problem of actually estimating the parameters of an identifiable problem is often an ill-posed problem, meaning that the estimated output may be close to the true output, while the parameters are still quite different from the true parameters. Moreover, such parameters are usually sensitive to slight perturbations of the data.

Suppose we are given a discrete set of observations/measurements made at times t_i , $i = 1, \dots, m$ such that

$$y_i = y(t_i) + \varepsilon_i, \quad (12)$$

where ε_i are assumed to be independent normal random variables with mean 0 and constant variance. The standard approach to estimation is to solve for A in the least-squares sense

$$\min_{A, B, C} \sum_i |y_i - y(t_i)|^2 \quad (13)$$

subject to the condition that A is a compartmental matrix of the appropriate model. (This is a nonlinear least-squares problem, since $y(t)$ is a linear combination of exponential functions.)

Another approach to estimation involves two stages; the data are first fitted to a sum of exponentials (Anderson, 1983)

$$g(t) = \sum_{k=1}^n c_k e^{\lambda_k t}. \quad (14)$$

In most nonpathological cases, the number of exponentials to be considered is the same as the size of the model. The estimates $\hat{c}_k$ and $\hat{\lambda}_k$ are obtained by least squares subject to $\lambda_k \leq 0$. Then, the Laplace transform of the fitted function $g(t)$ is compared with the Laplace transform of $y(t)$. As both are rational functions, the numerator and denominator are polynomials whose coefficients must be approximately equal.

There is also the method of peeling, which avoids least squares. This involves fitting an exponential function to the later data values. This corresponds to the eigenvalue of smallest magnitude. The difference between the data and this function is then used to approximate the second eigenvalue, and so on.

COMPLEX GINZBURG–LANDAU EQUATION

Ginzburg–Landau (GL) is a generic name for a class of basic models of nonlinear science, with a wide range of applications. They combine most fundamental features that underlie pattern formation in nonlinear media: dissipation (linear and nonlinear) and gain (provided by an intrinsic instability), conservative nonlinearity (accounting for wave mixing), and diffusion and/or dispersion (dependence of the dissipation rate and wave frequency on the wave number). Usually, the diffusion

and dispersion are linear, but in more sophisticated models they may be both linear and nonlinear. In most cases, GL equations are local, but nonlocal (integral) generalizations are sometimes used. Both single GL equations and systems thereof play important roles as fundamental models.

The name of this class of equations first appeared in a seminal paper by Vitaly Ginzburg and Lev Landau (1950), which presented a phenomenological theory of superconductivity (V.L. Ginzburg was awarded the Nobel Prize in Physics in 2003 for this work.) In a standard form (Tinkham, 1996), these equations are

$$\begin{aligned} \eta (\partial_t + i\kappa\phi) \psi &= - (i\kappa^{-1} \nabla + \mathbf{A})^2 \psi \\ &\quad + (1 - |\psi|^2) \psi, \quad (1) \\ \mathbf{A}_t + \nabla\phi &= -\nabla \times (\nabla \times \mathbf{A}) + (2i\kappa)^{-1} \\ &\quad \times (\psi^* \nabla \psi - \psi \nabla \psi^*) - |\psi|^2 \mathbf{A} \\ &\quad + \nabla \times \mathbf{H}, \quad (2) \end{aligned}$$

where ψ is the wave function of superconducting electrons, also known as the order parameter of the superconductivity, $\mathbf{A}$ and $\mathbf{H}$ are the vector potential of the intrinsic magnetic field and an externally applied field, ϕ is the electrostatic potential (related to $\mathbf{A}$ by an arbitrary gauge condition, e.g., $\phi_t + \nabla \cdot \mathbf{A} = 0$), η and κ are the dissipative and so-called GL parameters, ∇ is the gradient, and subscripts stand for the partial derivatives. A solution with $\psi = 0$ represents a normal state with no superconductivity. In their original work, Ginzburg and Landau (1950) introduced a time-independent version of the equations, while the full time-dependent system was proposed later.

In the modern theory of nonlinear pattern formation (Cross & Hohenberg, 1993), the name GL is applied to equations resembling Equation (1) [while there is usually no counterpart of Equation (2)], which govern the evolution of a physically or phenomenologically defined order parameter in a dynamical medium. For instance, in the case of chemical-reaction waves, the order parameter determines local concentrations of reactants (Ipsen et al., 2000); in applications to fluid mechanics, the velocity field is expressed in terms of the order parameter, and in numerous applications to optics the order parameter is a local amplitude of the electromagnetic field (Arecchi et al., 1999).

The first generic example of the GL equation of this type is the complex cubic GL (CCGL) equation (“cubic” refers to the nonlinearity), which is closest in its form to Equation (1), but the name “complex” stresses that its coefficients are complex:

$$\psi_t = g\psi + (a + ib) \nabla^2 \psi - (d + ic) |\psi|^2 \psi. \quad (3)$$

The first term on the right-hand side of Equation (3) accounts for the gain, provided that $g > 0$ (its imaginary part can be trivially removed), a and b are real coefficients accounting for the diffusion and

dispersion, while d and c are parameters controlling the nonlinear dissipation and frequency shift. Note that a and d must be positive, otherwise (3) is an ill-posed equation. In the case $|a| \ll |b|$, $|d| \ll |c|$, Equation (3) may be treated as a perturbed version of the nonlinear Schrödinger (NLS) equation.

In the case $b=c=0$, Equation (3) is called a real GL equation, to stress that all its coefficients are real, although ψ remains complex. The real GL equation may be represented in the gradient form, $\psi_t = -\delta L\{\psi, \psi^*\}/\delta\psi^*$, where $\delta/\delta\psi^*$ stands for the functional derivative, and $\int (-|\psi|^2 + |\nabla\psi|^2 + (1/2)|\psi|^4) dV$ is a real Lyapunov functional. A consequence of the gradient representation is that L may only decrease, $dL/dt \leq 0$. This fact simplifies the dynamics of the real GL equation.

A fundamental feature of Equation (3) is that its zero solution, $\psi=0$, becomes unstable as the gain g changes its sign from negative to positive. In this case, a transition from the stable trivial solution to a nontrivial state is called *supercritical*. In particular, the supercritical transition in the one-dimensional (1-d) case yields a solitary-pulse (SP) solution that can be found in an exact analytical form,

$$u = A [\cosh(\kappa x)]^{-(1+i\mu)} \exp(-i\omega t), \quad (4)$$

where A , κ , μ , and ω are uniquely determined by parameters of Equation (3). If the CCGL equation reduces to a perturbed NLS equation, the SP (4) can be obtained from the NLS soliton by means of the perturbation theory, provided that $bc < 0$ (otherwise, the NLS equation does not have bright-soliton solutions). However, the SP solution (4) is always unstable because the zero background around it is unstable.

In many cases (for instance, in the case of thermal convection in a binary fluid), a nontrivial state may be excited by a finite-amplitude perturbation, while the trivial solution is stable against small perturbations. The simplest model that describes the corresponding *subcritical* transition to a nontrivial state is the cubic-quintic complex GL (CQCGL) equation, first proposed by Petviashvili and Sergeev (1984) as

$$\psi_t = -g\psi + (a+ib)\nabla^2\psi + (d-ic)|\psi|^2\psi - (f+ih)|\psi|^4\psi. \quad (5)$$

Here, $g > 0$ implies stability of the zero solution, the last term with $f > 0$ guarantees overall stabilization of the system, the coefficient h accounts for a quintic nonlinear correction to the wave frequency, while $d > 0$ provides for a possibility of *nonlinear* gain. The CQCGL equation may give rise to nontrivial states, coexisting with the stable zero solution, if the nonlinear gain coefficient exceeds a value $d_{\min} = 2\sqrt{gf}$. An important result, obtained by means of analytical and numerical methods, is that the 1-d and 2-d versions of

the CQCGL equation support SP solutions that may be *stable* (in the 2-d case, the localized pulse may carry vorticity, having a spiral structure). If all the parameters g , a , d , f , and h are small, the 1-d pulse can be constructed on the basis of the NLS solution by means of the perturbation theory. However, the CQCGL equation does not make it possible to find stable SP solutions in an exact analytical form (one exact solution for a 1-d SP is known, but it is always unstable).

Patterns in nonlinear dissipative media may be supported not only by intrinsic gain; another possibility is to apply an external field, which is, for instance, the case for the pattern formation in laser cavities (Arecchi et al., 1999). In this case, the appropriate CCGL equation is

$$\psi_t = -g\psi + (a+ib)\nabla^2\psi - (d+ic)|\psi|^2\psi + P, \quad (6)$$

where the driving term, induced by the external field, may be of two different types: direct drive, $P = \varepsilon$, or parametric drive, $P = -i\omega_0\psi + \varepsilon\psi^*$, where the asterisk stands for complex conjugation, ω_0 fixes the frequency, and ε is the drive's amplitude. Equation (6) with either type of drive can support stable SPs in 1-d and 2-d cases (in the case of the direct drive, SP settles on a nonzero background).

An important generalization is to consider systems of coupled GL equations. These may describe counter-propagating waves (for instance, in thermal convection in a binary-fluid layer), or second-harmonic generation in a lossy medium. In the latter case, the nonlinearity is not cubic, but *quadratic*, viz., $\psi_1^*\psi_2$ in the equation for the fundamental-frequency field ψ_1 , and ψ_1^2 in the equation for the second-harmonic field ψ_2 .

An alternative to the CQCGL equation is a system originating in nonlinear optics, in which the stability of the zero solution is provided by an extra linear equation,

$$\begin{aligned} \psi_t &= g\psi + (a+ib)\nabla^2\psi - (d+ic)|\psi|^2\psi - i\kappa\chi, \\ \chi_t &= -G\chi - i\kappa\psi, \end{aligned} \quad (7)$$

where κ is a real coupling constant, and $G > 0$ is the loss coefficient in the additional equation. The zero solution in this system is stable if the loss in the second equation and coupling are strong enough, $G > g$ and $\kappa^2 > Gg$. System (7) has exact SP solutions, in which both fields ψ and χ take the form (4) (with different amplitudes), but, in contrast to the CCGL equation proper, in this case the pulse may be *stable* (Atai & Malomed, 1998).

Yet another type of a system occurs if, due to a specific nature of the underlying physical problem, the complex order parameter ψ is coupled to an extra real-order parameter ϕ , which accounts for the existence of a conserved quantity in the medium (Matthews & Cox, 2000): $\psi_t = \psi + \nabla^2\psi - |\psi|^2\psi - \phi\psi$, $\phi_t = \nabla^2[\sigma\phi + \mu(|\psi|^2)]$. In this simplest version of the system, $\sigma > 0$ and μ are real constants.

A common feature of the various GL equations displayed above is their universality. Each is a generic representative of a class of models with given qualitative properties (for instance, super- or subcritical character of the excitation of nontrivial states, and the absence or presence of a conserved quantity). In more specific situations, there arise generic equations of other types. In particular, the complex Swift–Hohenberg (SH) equation describes a situation (for instance, in Rayleigh–Bénard convection) when the instability of the zero solutions appears at a finite wave number k_0 of small perturbations; thus,

$$\psi_t = g\psi - (a+ib)(\nabla^2 + k_0^2)\psi - (d+ic)|\psi|^2\psi \quad (8)$$

with $g, a, d > 0$. Quasi-1-d solutions of Equation (8) can be looked for as $\psi(x, y, t) = \Psi(x, y, t) \exp(ik_0 x)$, where Ψ is a slowly varying function, whose x - and y -dependences are characterized by large scales $X, Y \gg k_0^{-1}$. An asymptotic consideration is then consistent in the case $X \sim Y^2$, reducing the SH equation (8) to an anisotropic complex Newell–Whitehead–Segel equation, $\Psi_t = g\Psi + (a+ib)(2i\partial_x + \partial_y^2)\Psi - (d+ic)|\Psi|^2\Psi$.

GL equations generate rich dynamics. The simplest exact solutions are plane waves (PWs). In the case of the CCGL equation (3) (here, it is set by rescaling $g = a = d \equiv 1$), a family of PWs is

$$\begin{aligned} \psi &= A \exp(iQx - i\omega t), \quad A = \sqrt{1 - Q^2}, \\ \omega &= c + (b - c)Q^2, \end{aligned} \quad (9)$$

where Q is a wave number (a parameter of the solution family) taking values $-1 < Q < +1$. Note that the group velocity of this PW is $d\omega/dQ = 2(b - c)Q$.

The CQGL equation gives rise to two different PWs for given Q , with amplitudes $A_{\pm} = (2f)^{-1} \times [1 \pm \sqrt{1 - 4f(1 + Q^2)}]$ (under the same normalization $g = a = d \equiv 1$). This solution exists in the interval $Q^2 < (4f)^{-1}(1 - 4f)$, and only A_+ may correspond to a stable PW.

The stability of PWs is an important issue. In the CCGL equation, a condition for stability against long-wave perturbations with a large wavelength takes a simple form, $Q^2 < (1 + bc) / (3 + 2c^2 + bc)$, which is called a generalized Eckhaus stability criterion (the original Eckhaus criterion, which applies to the real GL equation with $b = c = 0$, is $Q^2 < 1/3$). Obviously, this criterion cannot hold unless $1 + bc > 0$ (the Benjamin–Feir–Newell (BFN) condition). The consideration of finite-wavelength perturbations gives rise to more complex stability conditions. Therefore, following Aranson and Kramer (2002), the structure of a full stability region for the PWs can be shown by means of its cross sections in the space (b, c, Q) ; see Figure 1. The figure makes a distinction between convective

Figure 1. A set of cross sections of the stability region for the plane-wave solutions (9) of the cubic complex GL equation (3) in the space $(b, c, |Q|)$. The two top panels, the left bottom panel, and the right bottom panel show, respectively, the cross sections $b = \text{const}$, $b = -c$, and $c = \text{const}$. The filled circles mark turning points on the border between absolute and convective instabilities.

and absolute instabilities, when, respectively, the growing perturbation is traveling away or staying put. The transition from the 1-d CCGL equation to its multidimensional counterpart does not import extra instabilities to the PWs.

If the BFN combination $1 + bc$ becomes negative, the PW develops phase turbulence, which means that $|\psi|$ remains roughly constant, while the phase of the complex phase ψ demonstrates spatiotemporal chaos. In the 1-d case, close to the BFN instability threshold, the chaotic evolution of the phase gradient $p \equiv \phi_x$ obeys the Kuramoto–Sivashinsky equation, which, in a rescaled form, is $p_t + p_{xx} + p_{xxx} + pp_x = 0$. Deeper into the instability region, phase-slip points (PSPs) arise, at which the amplitude $|\psi|$ disappears. Multiple creation of PSPs leads to a transition from the phase turbulence to defect turbulence, which is distinguished by random dynamics of the PSP ensemble. Mixed turbulence at the border between these two types also occurs (Aranson & Kramer, 2002).

In the case when PWs are stable, shock waves can be generated by collision between two PWs (9) with different wave numbers Q_1 and Q_2 . Although exact solutions for shocks are not available, they can be obtained in an approximate form, provided that $Q_1 - Q_2$ is small, or the coefficients b and c are small. In particular, a transient layer between the two PWs moves at the velocity $v = (b - c)(Q_1 + Q_2)$, which is exactly the mean of the group velocities of the colliding PWs. In the 2-d case, PWs can collide obliquely; in this case, shocks take the form of a domain wall. Generally, the shocks are stable.

Besides the shocks (which are sources that emit PWs), the 1-d CCGL equation also gives rise to sinks,

that is, localized hole-type structures that absorb PWs. If the CCGL equation (3) is a perturbed version of the NLS equation, sinks can be constructed as perturbed counterparts of NLS dark solitons, provided that $bc > 0$ (particular solutions for the sinks are available in an exact analytical form). A standing sink is actually a PSP, as $|\psi|$ vanishes at its center, and it may be dynamically stable. A moving sink is a finite dip in the profile of $|\psi|$; it is structurally unstable, as it is either decelerated (turning into a standing sink) or accelerated (eventually vanishing) by a quintic term added to the CCGL equation (Lega, 2001; Aranson & Kramer, 2002).

The 2-d CCGL equation displays spiral waves (SWs) in the form $\psi = A(r) \exp(iN\theta - i\omega t)$, where r and θ are the polar coordinates, N is an integer vorticity, and $A(r)$ is a complex function. An asymptotic form of the SW is $A(r) \approx \sqrt{1 - Q^2} \exp(iQr)$ at $r \rightarrow \infty$, where Q is related to ω as in Equation (9), and $A(r) \sim r^N$ at $r \rightarrow 0$. (In the case of the real GL equation, the SW has $Q = 0$, which corresponds to a vortex solution. Similar solutions are generated by Equations (1) and (2), which represent *Abrikosov vortices* in superconductivity. For the prediction of these vortices, A.A. Abrikosov shared the Nobel Prize for Physics in 2003.) The asymptotic wave number Q is an eigenvalue of the 2-d CCGL equation, as it is uniquely selected by parameters of the equation. All the SWs with $N > 1$ are unstable. The SW with $N = 1$ may be subject to specific instabilities localized near its core (Aranson & Kramer, 2002).

An extension of the SW is a vortex line in three dimensions, which, in particular, may be closed into a ring. A vortex line with an additional wave number directed along its axis (twisted vortex) is also possible. The dynamics of 3-d vortex lines are quite complicated (Aranson & Kramer, 2002).

CONLEY INDEX

In a five-page paper published in the Proceedings of the 1970 International Congress of Mathematicians (Conley, 1971), Charles Conley gave the first definition of his index. For context, he chose the phase space to be a compact connected metric space X and F to be the space of flows on X with the compact open topology. (A flow is a continuous function such that $f(x, 0) = x$, $f(x, t + s) = f(f(x, t), s)$ for all choices of x, t, s .)

For a compact subset Y of X define the set $\text{Inv}(Y, f) = \{y \in Y : f(y, t) \in Y \text{ for all } t\}$. This set is the maximal invariant set contained in Y . An isolating neighborhood for a flow f is a compact subset N of X such that $\text{Inv}(N, f)$ is contained in the interior of N . The set, $\text{Inv}(N, f)$, is the isolated invariant set associated with N .

It is easy to show that isolating neighborhoods persist. If N is an isolating neighborhood for f , then there exists a neighborhood U of f in F such that N is an isolating neighborhood for every flow g in U . Suppose that M is an isolating neighborhood for g . If $\text{Inv}(M, g) = \text{Inv}(N, g)$ then the isolated invariant set $\text{Inv}(M, g)$ is said to be a local continuation of the set $\text{Inv}(N, f)$. Two invariant sets $\text{Inv}(N, f)$ and $\text{Inv}(M, g)$ are related by continuation if there is a finite sequence of local continuations linking one to the other.

For a flow f and an arbitrary compact subset W of X , one defines forward and backward exit time functions from W into the extended real line $[-\infty, \infty]$ as follows:

$$t^+(x) = \sup\{t \geq 0 : f(x, [0, t]) \subset W\},$$

$$t^-(x) = \inf\{t \leq 0 : f(x, [t, 0]) \subset W\}.$$

Certain subsets of W are associated with these functions. The forward asymptotic set is the set $A^+ = \{x : t^+(x) = \infty\}$, and the backward asymptotic

set is the set $A^- = \{x : \tau^-(x) = -\infty\}$. Note that the maximal invariant set $\text{Inv}(W, f)$ is the set $A^+ \cap A^-$. Forward and backward exit sets are the sets $W^\pm = \{x : \tau^\pm(x) = 0\}$.

An isolating block B for a flow f is a special type of isolating neighborhood with the following property. The boundary of B is the union of the exit sets B^+ and B^- . The intersection of these sets is the "tangency" set τ of boundary points that immediately exit in both time directions. Thus, a block has no internal tangencies where an orbit comes to the boundary from inside the block and does not exit.

If B is an isolating block for a flow f , one can show that the exit time functions are continuous. Using these functions and the flow, one may define deformation retractions of $B - A^+$ onto B^- and $B - A^-$ onto B^+ . For example, a retraction r of $B - A^-$ onto B^+ is defined by the formula $r(x) = f(x, \tau^+(x))$ (This property was first used by Wazewski (1954).)

Suppose that f is a flow on R^3 and also that T is a solid torus that is an isolating block for the flow. Suppose that the exit set is a disk D on the boundary of T . Then, the invariant set $\text{Inv}(T, f)$ must not be empty. If it were empty, one could define a deformation retraction of T onto D , which is impossible.

Under these definitions, the following theorem is fundamental (Conley & Easton, 1971). Given an isolating neighborhood N for a flow f , there exists an isolating block B contained in N such that $\text{Inv}(N, f) = \text{Inv}(B, f)$.

We use this theorem to define the Conley index of the set $\text{Inv}(N, f)$ to be the homotopy types of the pair of quotient spaces $[B/B^+]$ and $[B/B^-]$. These spaces are obtained by collapsing the exit sets to points and using the quotient topology on the resulting spaces.

Consider, for example, the flow f defined on R^2 by $f((x, y), t) = (e^{-t}x, e^ty)$. This flow has the origin as a saddle point. Let B be a square centered at the origin. Then B is an isolating block for the flow. The exit set consists of the top and bottom sides of B . The quotient space $[B/B^-]$ has the homotopy type of the pair of spaces consisting of a circle and a point on this circle.

The Conley Index has the following properties (Conley, 1978; Herman et al., 1988; Smoller, 1983; Easton, 1998; Hofer & Zehnder, 1995; Mischaikow, 2002):

- (i) The Conley index is well defined. Thus it is independent of the choice of block B .
- (ii) If $\text{Inv}(N, f)$ and $\text{Inv}(M, g)$ are two isolated invariant sets that are related by continuation, then they have the same Conley index.
- (iii) The index $[B/B^-]$ of a saddle point for a smooth flow on a manifold is a sphere together with a point on the sphere. The sphere has the same dimension as that of the unstable manifold of the saddle point.

Thus, the Conley index is a generalization of the Morse index of a saddle point.

- (iv) The index of two disjoint isolated invariant sets is the "sum" or "join" of their indices.

Traveling Waves

One of the early applications of the Conley index was to find traveling waves for reaction-diffusion equations (Smoller, 1983). We will use as an example the FitzHugh-Nagumo (FN) equations $u_t = \varepsilon v$, $v_t = v_{xx} + f(v) - u$, which are a simplification of the Hodgkin-Huxley equations used to model nerve impulses. The parameter ε is assumed to be small, and one seeks a solution of the form $U(x, t) = u(s)$, $V(x, t) = v(s)$, where $s = x + \theta t$ and θ is the wave velocity.

Substituting the trial solutions into the FN equations, one obtains the following system of ordinary differential equations: $du/ds = (\varepsilon/\theta)v$, $\theta dv/ds = d^2v/ds^2 + f(v) - u$, where $f(v)$ is assumed have the general shape of a cubic equation that is decreasing, increasing, and then decreasing. To be specific, we take $f(v) = -v(v-1)(v-2)$. The corresponding first-order system of ordinary differential equations is $u' = \sigma v$, $v' = w$, $w' = \theta w + u - f(v)$, where $\sigma = \varepsilon/\theta$. Our goal is to find a periodic solution of this system for small values of the parameters σ and θ , and thereby to find a periodic solution of the FN equations.

One can completely understand the phase portrait of system when the parameters σ and θ are set to zero. In this case, $u(t)$ is constant and the equations for v, w form a Hamiltonian system with Hamiltonian $H(v, w) = w^2/2 + F(v) - uv$ with $F(v) = \int_0^v f(r)dr = -v^2(v-2)^2/4$. The phase portrait in the $u=0$ plane has saddle points at $(v, w) = (0, 0)$, $(v, w) = (2, 0)$ and a center at $(v, w) = (1, 0)$. The saddle points are connected by heteroclinic orbits implicitly defined by the equation $H(v, w) = 0$, $0 < v < 2$. Note that the set of equilibrium points for the system is the set $\{(u, v, w) : u = f(v), w = 0\}$.

Next consider the system with $\sigma = 0$, $\theta > 0$. For this system, we have $(d/dt)H(u(t), v(t), w(t)) = \theta w^2(t)$. Let $a(u) < b(u) < c(u)$ denote the three solutions of the cubic equation $u - f(u) = 0$. One can show that there are values $0 < u_1 < u_2$ such that for $j = 1, 2$, there is a heteroclinic solution joining the equilibrium points $(u_j, a(u_j), 0)$ and $(u_j, c(u_j), 0)$ in the plane $u = u_j$. We now have a cycle consisting of the two heteroclinic orbits together with arcs of equilibrium points $\{(u, a(u), 0) : u_1 < u < u_2\}$ and $\{(u, c(u), 0) : u_1 < u < u_2\}$. This cycle is an invariant set for the system. However, the cycle is not isolated since it intersects the set of equilibrium points in two arcs. The two arcs of equilibrium points may be viewed as normally hyperbolic invariant manifolds, whose stable

and unstable manifolds intersect transversally along the two heteroclinic orbits.

Finally, consider the system for small positive values of σ . In this case, u is increasing when u is positive and decreasing when negative. The hard part is to construct an isolating block, which topologically is a solid torus containing the cycle. The transversal intersection noted above is essential to this construction. The cycle is no longer invariant when σ is positive. However, one shows that the isolating block must contain a periodic solution of the full system of equations. The periodic solution thus constructed may be viewed as a periodic traveling wave solution of the FN equations.

Applications to Discrete Dynamical Systems

Consider the discrete dynamics generated by iterating a homeomorphism f of a compact metric space X . It is natural to study orbits with "errors" such as truncation or round-off errors in numerical algorithms. Thus, an ε -chain for f is a finite sequence $(y_0, y_1, y_2, \dots)$ such that $d(f(y_n), y_{n+1}) \leq \varepsilon$ where $d(x, y)$ is the distance function on X . Conley (1978) and Bowen (1975) both understood the importance of studying orbits with errors. Bowen asked when such an orbit could be shadowed by a true orbit of the system.

Conley defined the ε -chain recurrent set $\text{CR}(f, \varepsilon)$ to be the set of points that are contained in periodic ε -chains of length at least 2. The chain recurrent set is the set $\text{CR}(f) = \bigcap \{\text{CR}(f, \varepsilon) : \varepsilon > 0\}$. Points in $\text{CR}(f)$ are chain equivalent if for any positive ε there is a periodic ε -chain containing both points. He showed that every orbit uniformly approaches a unique chain equivalence class in $\text{CR}(f)$. This result is known as the Conley decomposition theorem, and it generalizes Smale's decomposition of an Axiom A system into basic sets (Bowen, 1975).

An isolating block for f is a compact subset N of X such that whenever $x, f(x), f^2(x) \in N$, then $f(x)$ is contained in the interior of N . This is something like having no internal tangencies. The exit set of N is the set $E = \{x \in N : f(x) \ni \text{int}(N)\}$. Because N is a block, the exit set is compact. Define an equivalence relation on N making all points of E equivalent and all points not in E equivalent only to themselves. Let $N^\#$ denote the space of equivalence classes with the quotient topology obtained by projecting N onto $N^\#$ by sending a point to the equivalence class to which it belongs. Let $E^\#$ denote the image of E . The index space of N is the pair $(N^\#, E^\#)$. Define an index map $f^\# : N^\# \rightarrow N^\#$ by $f^\#(x) = E^\#$ if $x = E^\#$ or $f(x) \in E^\#$. Otherwise, define $f^\#(x) = f(x)$. Note that the index map is continuous. The pair $(N^\#, f^\#)$ plays the role of the Conley index in this context. If the index map is not homotopic to a constant, then one can prove that the set $\text{Inv}(N, f)$ is non-empty.

Smale's horseshoe map in the plane may be used as an example. Suppose that a rectangle B is mapped across itself so that the image crosses the rectangle in a horizontal strip, then curves back and crosses the rectangle again in another horizontal strip above the first. In this case, the exit set consists of three vertical strips, one in the center of the rectangle and the other two on the left and right sides containing the vertical edges of B . The index space $[B/B^-]$ has the homotopy type of a figure of eight and the index map is non-trivial.

Sequences of compact sets (called "windows") may sometimes be constructed to contain an orbit with errors. If each window in the sequence is "correctly" mapped across the next one, then a true orbit runs through the sequence of windows and shadows the orbit with errors (Easton, 1998).

CONSTANTS OF MOTION AND CONSERVATION LAWS

Although nonlinear spatiotemporal processes may be very complicated, they frequently obey simple constraints in the form of conservation laws. It is sometimes possible to construct one or several constants of motion (also called dynamical invariants, DIs), in the form of spatial integrals of local densities expressed in terms

of the physical fields and their derivatives, which are conserved in time, as a consequence of the underlying dynamics. Such commonly known conserved quantities as energy, momentum, and angular momentum belong to this class.

Typically, the existence of conservation laws can be established if the underlying dynamics is dissipation-free; however, a specific DI may sometimes also exist in dissipative systems. Examples of the latter are provided by the diffusion equation, $u_t = u_{xx}$, and its important nonlinear counterparts in the form of the Burgers equation,

$$u_t = u_{xx} + uu_x, \quad (1)$$

and Cahn–Hilliard equation,

$$u_t + (u - u^3 + u_{xx})_{xx} = 0 \quad (2)$$

(the subscripts stand for the partial derivatives). They all conserve $\int_{-\infty}^{+\infty} u(x, t) dx$, which is simply the total mass of the substance in the case of diffusion.

A more sophisticated example of the “dissipative conservation” occurs in physically important models based on the nonlinear Schrödinger (NLS) equation with special additional terms:

$$iu_t + u_{xx} + F'(|u|^2)u = \varepsilon Q, \quad (3)$$

where the function F' describes conservative nonlinearity of the medium (the prime stands for the derivative with respect to the argument of F ; in particular, $F = (|u|^2)^2$ corresponds to the most generic case of the cubic NLS equation), ε is a real parameter, and the “special perturbation” is, for instance, the nonlinear Landau-damping term in the NLS equation for Langmuir waves in plasmas,

$$Q = -u \int_{-\infty}^{+\infty} dx' (x - x')^{-1} |u(x')|^2, \quad (4)$$

or the stimulated Raman scattering term in the equation for electromagnetic waves in nonlinear optical fibers, $Q = (|u|^2)_x u$. While these terms are dissipative ones, the corresponding perturbed NLS equation conserves the single DI, namely, the total *wave action* (alias “number of quanta”),

$$N = \int_{-\infty}^{+\infty} |u(x, t)|^2 dx. \quad (5)$$

In the general case, equations that govern the dissipation-free spatiotemporal dynamics can be derived from the underlying action functional $S\{u^{(n)}\}$: $\delta S/\delta u^{(n)} = 0$, where $u^{(n)}(\mathbf{r}, t)$ is the n th field variable, $\mathbf{r}$ is the set of the spatial coordinates, $\delta/\delta u^{(n)}$ stands for the variational (functional) derivative, and the

action is expressed in terms of the Lagrangian density $\mathcal{L}$, so that

$$S = \int \int \mathcal{L}(u^{(n)}, \nabla u^{(n)}, u_t^{(n)}) d\mathbf{r} dt. \quad (6)$$

For instance, the density

$$\mathcal{L} = (1/2)[u_t^2 - (\nabla u)^2] - F(u) \quad (7)$$

yields a nonlinear Klein–Gordon (NKG) equation for a single real field u ,

$$u_{tt} - \nabla^2 u + F'(u) = 0. \quad (8)$$

The fundamental nature of DIs in Lagrangian systems is established by a theorem that was published by Emmy Noether in 1918: any *continuous symmetry* of the system, that is a family of transformations of the field variables, spatial coordinates, and time, which depend on an arbitrary continuous parameter ξ and leave the action invariant, generates a constant of motion. If the infinitesimal symmetry transformation is written in the form

$$\begin{aligned} u^{(n)} &\rightarrow u^{(n)} + U_n d\xi, \quad \mathbf{r} \rightarrow \mathbf{r} + \mathbf{R} d\xi, \\ t &\rightarrow t + T d\xi, \end{aligned} \quad (9)$$

then the main result following from the Noether theorem is the continuity equation $\mathcal{I}_t + \nabla \cdot \mathbf{J} = 0$, with the following density and current:

$$\begin{aligned} \mathcal{I} &= \sum_n \frac{\partial \mathcal{L}}{\partial (u_t^{(n)})} \left(\mathbf{R} \cdot \nabla u^{(n)} + T u_t^{(n)} - U_n \right) \\ &\quad + T \mathcal{L}, \\ \mathbf{J} &= \sum_n \frac{\partial \mathcal{L}}{\partial (\nabla u^{(n)})} \left(\mathbf{R} \cdot \nabla u^{(n)} + T u_t^{(n)} - U_n \right) \\ &\quad + \mathbf{R} \mathcal{L}, \end{aligned} \quad (10)$$

($\partial/\partial (\nabla u^{(n)})$ is realized as a vector with the components $\partial/\partial (u_x^{(n)})$, $\partial/\partial (u_y^{(n)})$, $\partial/\partial (u_z^{(n)})$). Then, assuming, as usual, that the fields disappear at $|\mathbf{r}| \rightarrow \infty$, the continuity equation immediately yields the conservation law in the form of $dI/dt = 0$, with $I \equiv \int \mathcal{I} d\mathbf{r}$. A detailed derivation of this fundamental result can be found in the book by Bogoliubov & Shirkov (1973); for discussion of the Noether theorem in various contexts, see also Sulem & Sulem (1999), and Whitham (1974). If the underlying equations are complex, the Lagrangian density and all the DIs are nevertheless real.

The obvious invariance of the action against arbitrary temporal and spatial shifts, which are described by Equation (9) with $U_n = 0$ and, respectively, $\mathbf{R} = 0$, $T = 1$, or $\mathbf{R}_j = \mathbf{e}_j$, $T = 0$ ($\mathbf{e}_j$ is the unit vector corresponding to the j th spatial coordinate) gives rise

to the conservation of the energy (Hamiltonian) H and momentum P . For the important classes of the NKG and multidimensional NLS, Equations (8) and (3), Equation (10) yields

$$H_{\text{NKG}} = \int \left[\frac{1}{2} (u_t^2 + (\nabla u)^2) + F(u) \right] d\mathbf{r},$$

$$P_{\text{NKG}} = - \int u_t \nabla u \, d\mathbf{r}, \quad (12)$$

$$H_{\text{NLS}} = \int [|\nabla u|^2 - F(|u|^2)] d\mathbf{r},$$

$$P_{\text{NLS}} = i \int (u \nabla u^* - u^* \nabla u) d\mathbf{r}, \quad (13)$$

where $*$ stands for the complex conjugation (the transition from the Lagrangian to Hamiltonian density as per Equation (10) in the case of the temporal-shift invariance is called the Legendre transformation). The invariance against rotations in the three-dimensional space leads to the conservation of the angular momentum,

$$M = \int (\mathbf{r} \times \mathcal{P}) d\mathbf{r}, \quad (14)$$

where $\mathcal{P}$ is the density in the expressions for the momentum in Equations (12)–(14); in the two-dimensional case, there is only one component of the conserved angular momentum. Additionally, in the NLS-type equations, the invariance against the phase shift (alias *gauge invariance*), $u \rightarrow u \exp(i\xi)$ with an arbitrary constant ξ , generates the conservation of the above-mentioned wave action (5), which is $\int |u|^2 d\mathbf{r}$ in the multidimensional case.

Another important class of models in one dimension is based on equations of the Korteweg–de Vries (KdV) type for a real function $u(x, t)$,

$$u_t + u_{xxx} + F''(u)u_x = 0 \quad (15)$$

(the most important cases of the KdV equation proper and modified KdV equation correspond to $F = u^3$ and $F = u^4$, respectively). The Lagrangian representation of Equation (15) is possible in terms of the potential field v , defined so that $v_x \equiv u$, but the Hamiltonian and momentum are expressed solely in terms of the original field u ,

$$H_{\text{KdV}} = \int_{-\infty}^{+\infty} \left[\frac{1}{2} u_x^2 - F(u) \right] dx,$$

$$P_{\text{KdV}} = \int_{-\infty}^{+\infty} u^2 dx. \quad (16)$$

The invariance of the action, written in terms of the potential v , against the arbitrary shift $v \rightarrow v + \xi$ additionally generates the conservation of the “mass,” $\int_{-\infty}^{+\infty} u dx$.

Besides being a dynamical invariant, the Hamiltonian gives rise to a canonical representation of the equation(s) in the Hamiltonian form, which is dual to the Lagrangian representation. In particular, for the complex and real equations of the NLS and KdV types, respectively, this representation is

$$u_t = -i \frac{\delta H}{\delta u^*}, \quad u_t = \frac{\partial}{\partial x} \frac{\delta H}{\delta u}. \quad (17)$$

The conservation of H itself and the conservation of the mass in the KdV-type equations are immediate consequences of the general form of Equations (17). The conservation of the wave action in the NLS-type equation is also a consequence of its representation in the form of Equations (17).

If a multicomponent Lagrangian system possesses an additional (“isotopic”) symmetry against linear transformations of the components, this also gives rise to a specific DI. An important example is a system of coupled NLS equations of Manakov’s type (Manakov, 1973)

$$i \begin{pmatrix} u_t \\ v_t \end{pmatrix} + \nabla^2 \begin{pmatrix} u \\ v \end{pmatrix} + F'(|u|^2 + |v|^2) \begin{pmatrix} u \\ v \end{pmatrix} = 0, \quad (18)$$

which are invariant against rotation in the plane of (u, v) . In this case, Equation (10) gives rise to the DI (“isotopic spin”) in the form

$$S = i \int (uv^* - u^*v) d\mathbf{r}. \quad (19)$$

A very special situation arises for the DIs in the case of integrable equations, that is, those that are amenable to the application of the inverse scattering transform (IST) (Ablowitz & Segur, 1981; Newell, 1984; Zakharov et al., 1984). Integrable equations have an infinite set of hidden dynamical symmetries, which, unlike the above-mentioned elementary invariances against temporal and spatial shifts, spatial rotations, phase shift, etc., do not have a straightforward meaning. In compliance with the Noether theorem, each hidden symmetry generates the corresponding DI, which is an integral expression with a density that, unlike those corresponding to the elementary DIs (see Equations (12), (4), and (16), involves higher-order derivatives. For instance, in the integrable KdV equation (15) with $F = u^3$, the first higher-order DI is

$$I = \int_{-\infty}^{+\infty} (u_{xx}^2 + 5u^2 u_{xx} + 5u^4) dx. \quad (20)$$

In fact, it was an empirical discovery of several higher-order DIs in the KdV equation that was a major incentive for the study that had resulted in the discovery of the IST technique.

The IST provides a systematic method to derive the infinite set of the DIs in terms of the corresponding scattering data, into which the original wave field is mapped to make the hidden integrability explicit (Ablowitz & Segur, 1981; Newell, 1984; Zakharov et al., 1984). The use of the scattering data makes it possible to explicitly introduce a full system of the action-angle variables for the integrable equations, and demonstrate that the infinite set of the action variables is in one-to-one correspondence with the set of the DIs. It is also possible to prove; that all the DIs are *in involution* among themselves; that is, the Poisson bracket between any two DIs, defined as per the corresponding symplectic (Hamiltonian) structure, is zero. Thus, integrable equations are direct counterparts, for the case of the infinite number of degrees of freedom, of finite-dimensional Hamiltonian systems that are Liouville-integrable; that is, with a set of DIs that are in involution, their number being equal to the number of the degrees of freedom.

The presence of the infinite set of the DIs in the integrable equations helps to understand such a well-known property as the completely elastic character of collisions between solitons (Ablowitz & Segur, 1981; Newell, 1984; Zakharov et al., 1984): roughly speaking, the necessity to satisfy the infinite set of the conservation laws leaves no room for changes of the solitons, except for phase shifts. On the other hand, some equations amenable to the application of the IST technique, such as, for instance, the standard three-wave system,

$$(u_{1,2})_t + c_{1,2} (u_{1,2})_x = iu_{2,1}^* u_3, \quad (u_3)_t = iu_1 u_2, \quad (21)$$

where $u_{1,2}$ and u_3 are, respectively, the “daughter” and pump waves, and $c_{1,2}$ are group velocities, feature nontrivial “soliton reactions”—for instance, a spontaneous split of a pump-wave soliton into separating daughter ones. This possibility is explained by the fact that the above-mentioned one-to-one correspondence between the infinite sets of the degrees of freedom and DIs does not really hold for these equations: the set of the DIs is not “infinite enough” (Fokas & Zakharov, 1992). Such equations are sometimes called “solvable,” to stress their difference from the genuinely integrable ones (integrable in the sense of Liouville, as generalized to systems with infinitely many degrees of freedom).

Integrable lattice (discrete) models feature another important property: due to the lack of the continuous translational invariance, lattice systems lack the momentum conservation. Nevertheless, integrable lattice models do possess a conserved momentum, due to their hidden symmetry. For example, the Ablowitz–Ladik equation,

$$2i \frac{du_n}{dt} + (u_{n+1} + u_{n-1} - 2u_n) + |u_n|^2 (u_{n+1} + u_{n-1}) = 0, \quad (22)$$

which is an integrable discretization of the cubic NLS equation, conserves the real momentum in the form of

$$P = \sum_{n=-\infty}^{+\infty} (\psi_n \psi_{n+1}^* - \psi_n^* \psi_{n+1}). \quad (23)$$

In fact, conservation of the momentum is a specific integrability feature of discrete models, in contrast to continuum ones.

Elementary DIs find specific applications in systems perturbed by small nonconservative terms to order ε . In that case, the conservation laws no longer hold; however, using evolution (balance) equations for the former DI(s) is a convenient way to derive effective equations of motion for solitons (or other collective nonlinear excitations) in the weakly perturbed model. For instance, in the cubic NLS equation (3) with the above-mentioned terms (Kerr and stimulated Raman scattering ones), $F = (|u|^2)^2$ and $Q = (|u|^2)_x u$, an exact soliton solution with arbitrary amplitude η and velocity c , in the case of $\varepsilon = 0$, is

$$u_{\text{sol}} = \eta \operatorname{sech}(\eta(x - ct)) \times \exp[i(c/2)x + i(\eta^2 - c^2)t]. \quad (24)$$

In the presence of small $\varepsilon > 0$, the wave action (4) remains a DI (see above), and the balance equation for the formerly conserved momentum P_{NLS} , see Equation (13), is

$$\frac{dP}{dt} = 2\varepsilon \int_{-\infty}^{+\infty} [(|u|^2)_x]^2 dx. \quad (25)$$

Substitution of the unperturbed soliton (24) into Equation (25), and into the conservation of the wave action, yields evolution equations for the amplitude and velocity:

$$\frac{d\eta}{dt} = 0, \quad \frac{dc}{dt} = \frac{16}{15} \varepsilon \eta^4. \quad (26)$$

For further details and references, see the review by Kivshar & Malomed (1989).

CONTINUUM APPROXIMATIONS

In general, a physical system belongs to one of three broad classes: (i) media with distributed parameters (electromagnetic fields, fluids, or liquid), (ii) discrete media (crystal lattices, polymers, or macromolecules), and (iii) artificial periodic systems (layered structures, lattices of nano-dots, or Josephson arrays). In the first class, the dynamics of a system is described by partial differential equations (PDE) for the field variable $u(x, t)$ and in the other two cases by discrete differential equations (DDE) for the field variable at the lattice sites $u(n, t) = u_n(t)$. For simplicity, only one-dimensional (1-d) models are discussed here.

Well-known examples of discrete nonlinear dynamical systems include the following:

- The discrete 1-dimensional elastic chain with a nonlinear interaction between the nearest neighbors (generalized Fermi–Pasta–Ulam (FPU) model), whose equation of motion reads

$$m \frac{d^2 u_n}{dt^2} = \varphi'(u_{n+1} - u_n) - \varphi'(u_n - u_{n-1}), \quad (1)$$

where u_n is the displacement of the n th atom in a chain; a prime indicates the derivative with respect to the argument, and $\varphi(u_n - u_{n-1})$ is the energy of the interatomic interaction (Fermi et al., 1955). The particular choice $\varphi(\xi) = A\xi^2/2 + \alpha\xi^3/3 + \beta\xi^4/4$ and $\varphi(\xi) = c \exp(-p\xi) + q\xi$ represents α -FPU (for $\beta = 0$), β -FPU (for $\alpha = 0$), and Toda models.

- The discrete 1-d chain with linear interatomic interaction exposed to a nonlinear external field (discrete Frenkel–Kontorova (FK) model) with the following equation of motion:

$$m \frac{d^2 u_n}{dt^2} = A(u_{n+1} + u_{n-1} - 2u_n) - w'(u_n), \quad (2)$$

where $w(u_n)$ is the nonlinear on-site external potential. The particular choice $w = U(1 - \cos(2\pi u_n/a))$, where a is the interatomic distance, corresponds to the traditional FK-model (Frenkel & Kontorova, 1939).

- 1-d photonic crystals (periodic arrays of optical waveguides) or the discrete spin lattice, which may be described in the context of the discrete nonlinear Schrödinger equation (DNLS)

$$i \frac{d\psi_n}{dt} + B(\psi_{n+1} + \psi_{n-1} - 2\psi_n) + F(|\psi_n|^2)\psi_n = 0, \quad (3)$$

where in the simplest case F is a linear function of the argument. ψ_n denotes the value of the effective field at the n th element of the discrete system, which can be assigned different physical meanings for various applications.

Even in the 1-d case, the solution of the nonlinear DDE poses a fairly complicated mathematical problem and only a few of them can be solved exactly (the Toda and Ablowitz–Ladik equations). Thus, it is often easier to study discrete problems in the “continuum approximation” (CA) within the framework of PDEs. Clearly, some information about nonlinear dynamics of discrete systems is lost, and some phenomena cannot be described in this continuum limit; but in the long wave limit, this approach provides a good qualitative and even quantitative agreement with the results for a discrete system investigation.

In the CA, the discrete number of the atom site n is replaced with the continuous coordinate $x: na \rightarrow x$, with a being the interatomic equilibrium distance or the period of mesoscopic periodical structure, and $u_n(t) = u(na, t)$ is replaced with $u(x, t)$. The finite differences $u_{n\pm 1} - u_n$ have to be expanded in Taylor series

$$u_{n\pm 1} - u_n = \pm a \frac{\partial u}{\partial x} + \frac{a^2}{2} \frac{\partial^2 u}{\partial x^2} \pm \frac{a^3}{6} \frac{\partial^3 u}{\partial x^3} + \frac{a^4}{24} \frac{\partial^4 u}{\partial x^4} \dots \quad (4)$$

This expansion is valid under the condition

$$|(u_{n+1} - u_n)/u_n| \ll 1. \quad (5)$$

For linear waves of the form $u_n = u_0 \sin(kna - \omega t)$ this expansion agrees with the long wavelength approximation $ak \ll 1$, where k is a wave number.

Substitution of expansion (4) in DDE (1) in the leading approximation yields for the α -FPU and Toda models the Boussinesq equation

$$m \frac{\partial^2 u}{\partial t^2} - A a^2 \frac{\partial^2 u}{\partial x^2} - \frac{A a^4}{12} \frac{\partial^4 u}{\partial x^4} - 2\alpha a^3 \frac{\partial u}{\partial x} \frac{\partial^2 u}{\partial x^2} = 0. \quad (6)$$

(In the case of the β -FPU model, the modification of this equation with the nonlinear term $3\beta a^4 (\partial u / \partial x)^2 (\partial^2 u / \partial x^2)$ is obtained.)

Equations (2) for discrete FK model within continuum limit are transformed in the leading approximation into the nonlinear Klein–Gordon (NKG) equation

$$m \frac{\partial^2 u}{\partial t^2} - A a^2 \frac{\partial^2 u}{\partial x^2} + w'(u) = 0. \quad (7)$$

In the particular case of the periodic external potential $w = U(1 - \cos u_n)$, one obtains the sine-Gordon (SG) equation. Finally, the CA for DNLS equation (3) reduces to the usual partial differential nonlinear Schrödinger equation

$$i \frac{\partial \psi}{\partial t} + B a^2 \frac{\partial^2 \psi}{\partial t^2} + F(|\psi|^2) \psi = 0. \quad (8)$$

Examples (6)–(8) demonstrate that a different number of terms in expansion (4) are to be taken into account in different situations. In the case of Equation (1), the dispersion relation is

$$\omega = 2\sqrt{A/m} \sin ak/2, \quad (9)$$

which is of acoustic type with a weak dispersion in the limit $k \rightarrow 0$. Within the CA, this weak dispersion is governed by the fourth spatial derivative alone in expansion (4), and it is necessary to retain the dispersion term in (6). The dispersion relation for Equation (6) is consistent with the exact formula (9) only in the long wave limit $ak \ll 1$.

Unfortunately, the dispersion term $-(Aa^4/12) \partial^4 u / \partial x^4$ in (6) necessitates an additional boundary conditions for this equation and results in the appearance of additional nonphysical solutions with small frequencies and $ak \sim 1$. To avoid these side effects, a regularization of the expansion over the discreteness parameter a can be performed (Rosenau, 1987). This corresponds to substitution of the relation $\partial^2 / \partial x^2 \simeq (m/Aa^2) \partial^2 / \partial t^2$ into the dispersion term in (6) and leads to yet another version of the CA for Equation (1) containing the term with mixed derivatives:

$$m \frac{\partial^2 u}{\partial t^2} - A a^2 \frac{\partial^2 u}{\partial x^2} - \frac{m a^2}{12} \frac{\partial^4 u}{\partial x^2 \partial t^2} - 2\alpha a^3 \frac{\partial u}{\partial x} \frac{\partial^2 u}{\partial x^2} = 0. \quad (10)$$

The above estimation of CA application area ($ak \ll 1$) holds for long wave small amplitude envelope solitons in the nonlinear case as well. But in general, this condition can differ for solitons of different types. For example, CA descriptions of Boussinesq solitons of the type $u(x, t) = u(x - vt)$ describe the solutions of FPU model (1) only under the condition $v/v_c - 1 \ll 1$, where $v_c = \sqrt{Aa^2/m}$.

Only the lowest-order terms of expansion (4) have so far been taken into account for discrete systems within the CA. In general, retaining the next terms with higher powers of spatial derivatives exceeds the accuracy of CA. But in some way, such extended versions of the CA also take into account the discreteness of the systems and can lead to interesting and important physical results. Retaining the fourth order derivative in (4) transforms the nonlinear KGE (7) into

$$m \frac{\partial^2 u}{\partial t^2} - A a^2 \frac{\partial^2 u}{\partial x^2} - \frac{A a^4}{12} \frac{\partial^4 u}{\partial x^4} + w'(u) = 0. \quad (11)$$

In the case of a sinusoidal external force, the corresponding generalized equation (dispersive SG equation) has steady-state bounded kinks solutions (4π -kink solitons) for some particular values of their velocities (Bogdan et al., 2001). This result obtained within the CA is in agreement with the numerical result for the corresponding discrete system (2) (Alfimov et al., 1993). The inclusion of yet higher terms of expansion (4) in the nonlinear parts of discrete equations in the CA gives rise to the nonlinear dispersion and leads to an existence of exotic solitons such as “compactons” and “peakons.”

The CA is not restricted to the long-wave limit. For high-frequency short waves with wave numbers $k \simeq \pi/a$ and $\omega - \omega_{\max} \ll \omega_{\max}$ (where $\omega_{\max} = 2\sqrt{A/m}$ for (1) and (2)), the CA for the slowly varying envelope of antiphase oscillations ($u_n = (-1)^n v_n$) in the β -FPU-model results in a PDE with the Euclidean differential part

$$m \frac{\partial^2 v}{\partial t^2} + A a^2 \frac{\partial^2 v}{\partial x^2} + 4Av + 16\beta v^3 = 0. \quad (12)$$

The breather solution of this equation (Kosevich & Kovalev, 1975) within the CA describes the “intrinsic modes,” which are currently being widely discussed since the pioneering paper of Sievers and Takeno (1988). In more complicated diatomic chains with the gap in the linear waves spectrum at $k = \pi/2a$, the so-called “gap solitons” (breathers with frequencies lying in the gap) can be described in CA for the envelopes of the antiphase oscillations of atoms from two sublattices.

To this point, applications of the CA for DDE models of discrete systems were discussed. Often, the opposite approach is used where the corresponding PDEs are investigated numerically in some discrete

schemes as a system of DDE (Dodd et al., 1982). The finite-differences method is one of the most popular in this case: the initial function $u(x, t)$ is defined on the rectangular net of the (x, t) plane at points $x = hn, t = h't$. The partial derivatives are replaced by the finite differences

$$\begin{aligned}\frac{\partial u(x, t)}{\partial x} &= \frac{u_{n+1} - u_n}{h}, \quad \frac{\partial^2 u(x, t)}{\partial x^2} \\ &= \frac{u_{n+1} + u_{n-1} - 2u_n}{h^2}, \dots\end{aligned}\quad (13)$$

Generally, sampling over all variables is performed, but in some hybrid methods space sampling alone is carried out and the resulting system of ODEs is solved by using standard computer codes.

Space sampling is commonly used for complicated biological systems. In order to simulate the behavior of a single neuron, for example, its continuous structure may be sliced into a large number of small segments (compartments). This procedure is called the "compartmental" approach, and within it the continuous PDEs are replaced by sets of ODEs. The advantage of this modeling approach is that it imposes no restrictions on the properties of each compartment and permits great flexibility at the level of resolution. Compartmental methods make it possible to develop the realistic models that have a close relationship with the relevant experimental data.

CONTOUR DYNAMICS

A wide variety of fluid dynamical problems involve the material advection of a tracer field $q(\mathbf{x}, t)$, expressed by

$$\frac{Dq}{Dt} = \frac{\partial q}{\partial t} + \mathbf{u} \cdot \nabla q = 0, \quad (1)$$

where $\mathbf{u}(\mathbf{x}, t)$ is the fluid velocity. The value of q thus does not change following an infinitesimal element or particle. That is, for a particle at $\mathbf{x} = \mathbf{X}(\mathbf{a}, t)$, where $\mathbf{a}$ is a vector label (e.g., the initial position of the particle), Equation (1) implies that $q = q(\mathbf{a})$, a constant, and $\partial \mathbf{X} / \partial t = \mathbf{u}(\mathbf{X}, t)$, which is just the statement that the particle moves with the local fluid velocity. The collective effect of this transport is a rearrangement of the tracer field q by the velocity field $\mathbf{u}$.

Depending on the nature of $\mathbf{u}$, this may lead to highly intricate distributions of q , even starting from simple initial conditions. Moreover, there are important applications in which $\mathbf{u}$ depends on q itself, often in a nonlocal manner, that is, in which the entire field of q contributes to $\mathbf{u}$ at any given point $\mathbf{x}$. A specific example relevant to the present topic is provided by the two-dimensional Euler equations governing the behavior of an inviscid, incompressible fluid:

$$\frac{D\mathbf{u}}{Dt} = -\frac{\nabla p}{\rho}, \quad (2)$$

$$\nabla \cdot \mathbf{u} = 0, \quad (3)$$

where p is the pressure and ρ is the density (here constant), and where now the velocity field is two dimensional: $\mathbf{u} = (u, v)$. Taking the curl of Equation (2) gives an equation for the scalar vorticity $\zeta \equiv \partial v / \partial x - \partial u / \partial y$:

$$\frac{D\zeta}{Dt} = 0, \quad (4)$$

which is identical to Equation (1) if we take $q = \zeta$. Thus, the vorticity is materially conserved in this system. But it also induces the velocity field $\mathbf{u}$, that transports it. Equation (3) is satisfied generally by considering

$$u = -\partial \psi / \partial y \quad \text{and} \quad v = \partial \psi / \partial x, \quad (5)$$

where $\psi(\mathbf{x}, t)$ is called the streamfunction. Substituting these components into the definition of ζ leads to a Poisson equation for ψ :

$$\nabla^2 \psi = \zeta. \quad (6)$$

Given the distribution of ζ , this equation (with suitable boundary conditions) may be inverted to find ψ , whose spatial derivatives provide u and v . The inversion of

this equation can be formally accomplished by using the Green function $G(\mathbf{x}; \mathbf{x}')$ of Laplace's operator ∇^2 ; in two dimensions,

$$G(\mathbf{x}; \mathbf{x}') = (2\pi)^{-1} \log |\mathbf{x}' - \mathbf{x}|. \quad (7)$$

(G is the solution to Equation (6) for $\zeta = \delta(\mathbf{x}' - \mathbf{x})$, a singular delta distribution of vorticity having a unit spatial integral.)

Consider henceforth an unbounded two-dimensional fluid. Then, the formal solution to the inversion problem is

$$\psi(\mathbf{x}, t) = \iint G(\mathbf{x}; \mathbf{x}') \zeta(\mathbf{x}', t) d\mathbf{x}' dy', \quad (8)$$

which shows explicitly that the flow field at any point depends on the vorticity field at all points. Moreover, the integration over space implies that the field of ψ is generally smoother than that of ζ .

The evolution of the flow in this case consists of two basic steps:

- *inversion*—the recovery of the velocity field $\mathbf{u}$ from the distribution of ζ and
- *advection*—the transport of fluid particles to the next instant of time.

Now, a two-dimensional plane is carpeted by an infinite number of such particles, and therefore, this view of the evolution may appear to be quite complex. However, the material conservation of q (or ζ) affords an enormous simplification. First, note that, if one exchanges two particles labeled $\mathbf{a}$ and $\mathbf{a}'$ having the same value of q , this does not alter the distribution of q , and as a result the velocity field $\mathbf{u}$ remains unchanged. This is a "particle relabeling" symmetry, and in general, it gives rise to an infinite number of globally conserved quantities (the spatial integrals of any functional of q). This symmetry implies that contours of fixed q consist of the same set of fluid particles for all time. They are called material contours.

Contour dynamics arises from representing the distribution of q by a finite set of contours C_k , $k = 1, 2, \dots, n$, between which q is spatially uniform, and across which q jumps by Δq_k (defined to be the value of q to the left of C_k minus that to the right of C_k). The contours here are still material ones—the particles just on either side of a contour retain their distinct values of q . Between two contours, any two fluid particles may be exchanged without altering q or $\mathbf{u}$. This implies that only the contours matter for determining the velocity field. Also, since the contours are material, their advection suffices to evolve the entire distribution of q . This is the basis of contour dynamics.

To see how this works for the two-dimensional Euler equations, it remains to be shown as to how one can calculate the velocity field directly from the contours C_k . The starting point is Equation (8), in

which we consider $\zeta = q$ to be a piecewise-uniform field. For the moment, we need only use the property $G(\mathbf{x}; \mathbf{x}') = g(\mathbf{x}' - \mathbf{x})$ satisfied by the Green function of the Laplace operator. Also, we need only consider one contour at a time and afterwards linearly superpose the results, since the relation between q and $\mathbf{u}$ is linear. We may take $q = 0$ outside of the (closed) contour, so that $q = \Delta q$ inside it (denoted by the region R below). Nonzero exterior q simply gives rise to solid-body rotation, and may be superposed afterwards. Then, from Equation (5), we have

$$(u(\mathbf{x}, t), v(\mathbf{x}, t)) = \left(-\frac{\partial}{\partial y'}, \frac{\partial}{\partial x'} \right) \Delta q \iint_R g(\mathbf{x}' - \mathbf{x}) d\mathbf{x}' dy' \quad (9)$$

$$= -\Delta q \iint_R \left(-\frac{\partial}{\partial y'}, \frac{\partial}{\partial x'} \right) g(\mathbf{x}' - \mathbf{x}) d\mathbf{x}' dy' \quad (10)$$

$$= -\Delta q \oint_C g(\mathbf{X}' - \mathbf{x}) (dX', dY'), \quad (11)$$

where we have used the symmetry of g with respect to $\mathbf{x}$ and $\mathbf{x}'$ in the second line and Stokes' theorem in the third, and where $\mathbf{X}'$ denotes a point on the contour C . The velocity field anywhere thus depends only on the shape of C .

For a set of contours, the velocity field is required only on the contours themselves to evolve q . The contours thus form a closed dynamical system, contour dynamics, governed by

$$\frac{d\mathbf{X}_j}{dt} = \mathbf{u}(\mathbf{X}_j) = - \sum_{k=1}^n \Delta q_k \oint_{C_k} g(\mathbf{X}'_k - \mathbf{X}_j) d\mathbf{X}'_k \quad (12)$$

for all points $\mathbf{X}_j$ on contours C_j , $j = 1, 2, \dots, n$.

These equations were first derived for the two-dimensional Euler equations by Zabusky et al. (1979), following earlier work by Berk & Roberts (1967), who derived a similar contour-based model for the two-dimensional Vlasov equations in plasma physics. These authors also developed numerical methods for contour dynamics in which the contours were discretized into a finite set of points or nodes, originally connected by straight line segments. A wide variety of numerical methods have since been developed, many of which are summarized in the review articles of Dritschel (1989) and Pullin (1992). They principally differ in terms of the choice of the interpolation between nodes (linear, quadratic, cubic; local and global splines); the method of numerical quadrature used to evaluate the contour integral over the segment connecting adjacent nodes (trapezoidal, Gaussian, explicit); the method of redistributing, inserting, and removing nodes to maintain an accurate representation of the contour shape; and the procedure used, if any, to remove fine-scale structure (e.g., filaments and

thin bridges connecting two separating regions)—a procedure coined “contour surgery” (Dritschel, 1988).

Contour dynamics has been used to study a wide variety of problems, from the interaction of two vortex patches (having just one contour each), to the filamentation and stripping of nested vortices (having many contours to represent a continuum) (Dritschel, 1989; Pullin, 1992). The numerical method illustrated next is described in Dritschel (1988, 1989). This method uses local cubic splines between contour nodes, explicit quadrature to first order in the departure of the contour from a straight line between nodes, node redistribution based on maintaining a local node density proportional to the square root of contour curvature, and automatic surgery whenever contours or contour parts get closer than a prescribed cutoff scale δ . This scale and the precise formula for the node density are chosen to balance the errors arising from surgery and node redistribution. A fourth-order Runge–Kutta scheme is used for the time integration.

An example is presented next of the collapse of three vortex patches (see also (Rogberg & Dritschel, 2000)). The centers of the vortices are initially chosen at points where equivalent delta-distributed point vortices of the same circulation (spatial integral of q) are known to collide in finite time. Two of the vortices have $q = +2\pi$ and radii 1 and $2/\sqrt{5}$, while the third has $q = -2\pi$ and radius $\frac{2}{3}$. The two positive vortices are initially separated by a distance $d = 5$, and the negative vortex is placed at a distance $d\sqrt{17/27}$ and at an angle 225° relative to the joint center of the two positive vortices. The vortices are then all shifted so that the joint center of all three vortices lies at the origin. Starting from this configuration, the collapse time for the point vortices is 7.70059886...

Figure 1 illustrates the evolution of the vortices—in the upper left-hand frame, the initial conditions are shown, while the remaining frames (to the right and then downwards) are spaced at unit increments in time starting from $t = 5$ and ending at $t = 15$. By $t = 6$, the two positive vortices begin to merge (they are separated by only a thin channel of irrotational fluid). Thereafter, the flow grows rapidly in complexity, as many filaments are generated and small vortices roll up at the tips of some of the filaments. Notably, the negative vortex does not distort significantly, but merely acts to bring the two positive vortices together.

The complexity just illustrated is typical of many vortex interactions. An accurate, robust numerical method must be able to capture this generic behavior, at least over time scales when the flow is reasonably predictable. To see how well the current method performs, we next examine how the results vary with spatial resolution. Two additional simulations were performed at half and double the average point spacing used in Figure 1. The results are compared in Figure 2 at the final time, $t = 15$, when the numbers of nodes in the

Figure 1. The collapse of three vortex patches. The initial condition is shown in the upper left frame. Time proceeds to the right and downwards in increments of one unit, from $t = 5$ to $t = 15$. The window of view is $-5.0 < x < 5.0$ and $-5.8 < y < 4.2$. The negative vortex is rendered with a short-dashed line (with a dash between each node), while the positive vortices are rendered with a continuous solid line.

Figure 2. Comparison, at $t = 15$, of three contour dynamics simulations of vortex collapse. Resolution increases from left to right, doubling between each frame (the node spacing parameter is $\mu = 0.12, 0.06$, and 0.03 , and the large-scale length $L = 1$ in all cases; consult Dritschel (1989) or Dritschel & Ambaum (1997) for further details). The domain of view is the same as used in the previous figure.

three simulations are, from low to high resolution, 2740, 10,738 and 27,297 (at $t = 0$, the numbers of nodes are 183, 349, and 682). Note the cutoff scale $\delta = 0.000225, 0.0009$, and 0.0036 in the three simulations—there is a factor of 4 difference in δ between resolutions. The agreement is striking even in the detailed structure. The most visible differences show up in the lengths of the filaments, which are removed more readily at low resolution. These filaments, however, contribute negligibly to the velocity field, and retaining them makes little difference to the evolution of the flow.

Contour dynamics has since been applied in a variety of diverse fields. Its largest growth has occurred in the field of atmospheric and oceanic dynamics, where the potential vorticity plays the role of the materially

conserved tracer q often to a very good approximation (Hoskins et al., 1985). Indeed, its application to this field is on a much sounder footing than it is to the fields it was originally developed for: plasma physics and aeronautics. The two-dimensional approximation is a particularly severe one in aeronautics, since real flows do not preserve two-dimensional symmetry, unless constrained in some manner. In the atmosphere and oceans, rotation and stratification serve to constrain the flow to be two dimensional, or more appropriately, layerwise two dimensional, and furthermore one may extend contour dynamics to study such flows (indeed, the equations are formally no different than given those by (12); see (Dritschel, 2002)).

Finally, the use of contours to carry out tracer advection—the fast and accurate part of contour dynamics—has been combined with more traditional approaches of computing the velocity field (the inversion step) to produce a particularly fast, accurate, and versatile numerical method called the contour-advective semi-Lagrangian (CASL) algorithm (Dritschel & Ambaum, 1997; Dritschel et al., 1999; Dritschel & Viúdez, 2003). This latest development allows the extension of the contour approach to much more realistic sets of equations, and has significantly widened the applicability of the original contour dynamics method.

CONTROL PARAMETERS

See **Bifurcations**

CONTROLLING CHAOS

It may seem paradoxical that chaotic systems—which are extremely sensitive to the tiniest fluctuations—can be controlled; yet, the earliest reference to this idea appears around 1950, when John von Neumann presaged just that. Nowadays, laboratory demonstrations of the control of chaos have been realized in chemical, fluid, and biological systems, and the intrinsic instability of chaotic celestial orbits is routinely used to advantage by international space agencies who divert spacecraft to travel vast distances using only modest fuel expenditures.

A variety of techniques for chaos control has been implemented since around 1990 when the first concrete analyses appeared, including traditional feedback and open-loop methods, neural network applications, shooting methods, Lyapunov function approaches, and synchronization to both simple and complex external signals. These techniques resolve the paradox implied by chaos control in different ways, but they all make use of the fact that chaotic systems can be productively controlled if disturbances are countered by small and intelligently applied impulses. Just as an acrobat balances about an unstable position on a tightrope by the application of small correcting movements, a chaotic system can be stabilized about any of an infinite number of unstable states by continuous application of small corrections.

Two characteristics of chaos make the application of control techniques even more fruitful. First, chaotic systems alternately visit small neighborhoods of an infinite number of periodic orbits. The presence of an infinite number of periodic orbits embedded within a chaotic trajectory implies the existence of an enormous variety of different behaviors within a single system. Thus, the control of chaos opens up the potential for tremendous flexibility in operating performance within a single system.

As an example, Figure 1 depicts the Lorenz attractor, used to model fluid convection. Embedded within the gray attractor are innumerable periodic orbits, such as the solid figure-8 orbit and the more complicated dashed one. For practical systems such as chemical reactors or fluidized beds, the presence of multiple

Figure 1. Left: Lorenz attractor with two of its embedded unstable periodic orbits highlighted. Right: unstable points P_1 and P_2 in the surface of section indicated. The unstable direction is denoted by outgoing arrows, and stable direction is denoted by ingoing arrows.

co-existing states implies that one chaotic system could be operated in multiple different states, thus potentially performing the function of several separate units.

A second characteristic of chaos that is important for control applications is the exponential sensitivity of the phenomenon. That is, the fact that the state of a chaotic system can be drastically altered by the application of small perturbations means two things: such a system if uncontrolled can be expected to fluctuate wildly, and if controlled can be directed from one state to a very different one using only very small controls.

Traditional feedback control remains among the most widely used methods of control for chaotic systems. To implement feedback control, one waits until a chaotic trajectory by chance lands near a desired periodic point and then applies small variations to an accessible system parameter in order to repeatedly nudge the trajectory closer to that point. As an example, consider the plot to the right in Figure 1, where we depict two periodic points as they appear on a "surface of section" formed in this case by recording every intersection between the Lorenz chaotic attractor and the half plane, $Z = 0$, $X > 0$. To control the state to remain near point P_2 (so the trajectory stays near the figure-8 trajectory shown to the left), one needs to apply variations in a parameter, p , that directs the state toward P_2 along the unstable direction (or directions in more complicated problems) indicated by outgoing arrows in Figure 1. One can establish the direction in which a parametric control moves the chaotic state either experimentally, by varying the parameter and recording the future variation of the system state, or analytically, by determining the Jacobian of the flow or mapping where available. Nudging the state closer to P_2 amounts to what is termed "pole placement" in traditional control literature, and numerous reports of alternative strategies for selecting parameter variations appear in the literature. Strategies include simple pole placement, optimal control, neural network approaches, simple proportional control, periodic forcing, and control dependent on the distance from P_2 . Most of these strategies have proven successful under appropriate conditions, and the choice of strat-

egy depends principally on details of the control goal required and the computational resources available to meet that goal.

All of these strategies require that the system state must lie close to the desired state in order to achieve control. In such a case, the system dynamics can be linearized, making control calculations rapid and effective. Fortunately, in chaotic systems, one can rely on ergodicity to ensure that the system state will eventually wander arbitrarily close to the desired state. By the same token, if it is desired to switch the system between one accessible state (say P_1) and a second (say P_2), one can merely release control from P_1 and re-apply a new control algorithm once the system strays close to P_2 , which it is certain to do by ergodicity.

In higher-dimensional or slowly varying systems, the time taken for the state to move on its own from one state to another can be prohibitive, and for this reason fully nonlinear control strategies have been devised that use chaotic sensitivity to steer the system state from any given initial point to a desired state. Since chaotic systems amplify control impulses exponentially, the time needed to steer such a system can be quite short. These strategies have been demonstrated both in systems in which a large effect is desired using very modest parameter expenditures (energy or fuel) and in systems in which rapid switching between states is needed (computational or communications applications).

On the other hand, in both linear and nonlinear control approaches, one needs to repeatedly re-apply control over a time that is short compared with the inverse of the fastest growing growth rate of the system in order to counter the potential amplification of ubiquitous noises. Computational and experimental analyses have demonstrated that this is readily done in typical chaotic systems and that control can be robustly achieved. Because large but rare noise events can occur, however, controlled states occasionally break free when the system encounters an anomalous large noise. In this case, bounds have been established for the frequency and duration of these noise-induced excursions.

Numerous biological control applications have been proposed since the first introduction of the notion of chaotic control. Among the first applications were studies of intrinsic nonlinear control mechanisms involved in autonomic and involuntary functions such as the regulation of internal rhythms and the control of gait and balance. These studies confirm that nontrivial control algorithms are involved in the maintenance of normal physiological function and that provocative insights into pathological conditions can be gained (such as cardiac and breathing arrhythmias and motor tremor). Further work has shown that networks of chaotic devices, under prescribed conditions, can be brought into synchronization, and strong indications have been presented that neuronal signaling may rely on nonlinear synchronization. Additional experimental studies are promising for the control of unwanted fluctuations (e.g., during fibrillation of the heart) or for the so-called "anticontrol" of synchronized periodic signals in focal epilepsy. In both studies, the goal is to use feedback control methods to steer a diseased organ using small electrical stimulation: in the former state, toward a stabilized state, and in the latter, away from a synchronized state.

COSMOLOGICAL MODELS

Relativistic cosmology—the science of the structure and evolution of the universe—is based on the building and investigation of cosmological models (CMs), which describe geometrical properties of physical space-time, the matter, composition and structure of the universe, and physical processes at different stages of the universe's evolution. Prominent in cosmology is the hot big bang CM, which is based on solutions of Alexander Friedmann's cosmological equations for homogeneous isotropic models deduced in the framework of Einstein's general relativity theory (GR). Because of its large-scale structure (galaxies, clusters of galaxies, etc.), the universe is homogeneous and isotropic only on the largest scales from 100 Mpc. (The pc or parsec is an astronomical unit of distance equal to 3.2616 light years; thus, an Mpc is 3.2616 million light years.)

The most important feature of Friedmann's CM is its nonstationary character, which was confirmed by Edwin Hubble's discovery of cosmological expansion in 1929. In this formulation, the geometrical properties of physical space depend on the value of energy density ρ relative to a critical density

$$\rho_{\text{crit}} = \frac{3H_0^2}{8\pi G}, \quad (0)$$

where H_0 is the expansion rate (Hubble parameter) at the present epoch and G is Newton's gravitational constant. If $\Omega = \rho/\rho_{\text{crit}} = 1$, the 3-space is flat; if $\Omega > 1$, 3-space possesses positive curvature and if $\Omega < 1$, 3-space possesses negative curvature. Corresponding CMs are flat, closed, and open CM, respectively.

All Friedmann CMs have a beginning in time (or cosmological singularity), where energy density and curvature invariants diverge. Their evolutions depend on properties of matter. In the case of ordinary matter with a positive energy density and a nonnegative pressure, the evolution of flat and open models has the character of expansion, and closed models recollapse after an expansion stage. The assumption that the temperature was very high at the initial stage of cosmological explanation (hot CM) was confirmed by the discovery of the cosmic microwave background (CMB) radiation in 1965, with a present epoch temperature of about $T = 2.7$ K. The theory of nucleosynthesis of light elements (hydrogen, helium, deuterium, lithium, etc.) into the first few minutes of cosmological expansion based on the framework of the hot big bang CM is in accord with empirical data.

Advances in both theory and technology during the last 20 years have launched cosmology into a most exciting period of discovery. By using precise instruments (telescopes, satellites, spectroscopes), several cosmological research programs are being carried out, including investigations of the anisotropy

of CMB and supernovae observations. Cosmological observations have not only strengthened and expanded the hot big bang CM but they have also revealed surprises.

Recent measurements of the anisotropy of the CMB have provided convincing evidence that the spatial geometry is very close to being uncurved (flat) with $\Omega = 1.0 \pm 0.03$. The currently known components of the universe include ordinary baryonic matter, cold dark matter (CDM), massive neutrinos, the CMB and other forms of radiation, and dark energy. The sum of the values for these densities derived empirically is equal to the critical density (to within their margins of error). The largest contributions to energy density are from two components—CDM and dark energy. About 30% of the total mass-energy is dark matter, composed of particles probably formed early in the universe. Two thirds is in smooth dark energy whose gravitational effects began causing the expansion of the universe to speed up just a few billion years ago. The remarkable fact that the expansion is accelerating can be accounted for within GR, as the source of gravity is proportional to $(\rho + 3p)$, where the pressure p and energy density ρ describe the bulk properties of “the substance.” A substance with pressure more negative than one-third its energy has repulsive gravity in GR. Such a situation occurs, for example, for gravitating vacuum (positive cosmological constant), for which $p = -\rho$.

In addition to breakthrough empirical observations, creative theoretical ideas are also driving progress in cosmology. The development of cosmology during the last 20 years shows that profound connections exist between the elementary particles on the smallest scales and the universe on the largest. Using unified gauge theories of elementary particles, an inflationary scenario was formulated, which resolves a number of problems of standard Friedmann cosmology: flatness and the problem of horizon, among others. According to inflation, small bits of the universe underwent a burst of expansion when the universe was extremely young, explaining the homogeneity and isotropy of the universe at initial stages of cosmological expansion. Based on the framework of an inflationary CM, the appearance of quantum fluctuations with a nearly scale-invariant distribution by transition to radiation-dominated era was predicted, explaining the large scale structure of the universe.

The inflationary CM as well as others discussed above are singular, which is an outstanding problem of GR. Assuming that the Planck era (when the universe was sufficiently dense to require a quantum mechanical treatment) existed, some quantum gravitation theory is necessary to construct a regular CM. At present, the superstring theory is a candidate for such a theory.

Some regular CMs have been constructed in a “brane world,” under which our universe is thought to exist as a slice (or membrane) through a higher-dimensional

space. By using scalar fields with a negative potential, a solution for an oscillating CM was obtained; thus, the Big Crunch takes place in such models before Big Bang. Resolving the problem of cosmological singularity requires that the gravitation theory not only admits regular solutions for CM but also excludes singular solutions. This suggests gauge theories of gravitation (Poincaré gauge theory or metric-affine gauge theory), leading to regular bouncing solutions for CMs.

The building of more realistic CMs requires the resolution of fundamental cosmological problems. According to present knowledge, our universe is flat and 13 Gyr old, and it is expanding at the current rate of $H_0 = 72 \pm 8 \text{ km sec}^{-1} \text{ Mpc}^{-1}$. Measurements of the past rate reveal that the universe is presently in a period of cosmic acceleration. The contribution of ordinary matter to the overall mass energy is small, with more than 95% of the Universe existing in new and unidentified forms of matter and energy. What is the composition of dark matter (axions, neutralinos, or other exotic particles)? What is the nature of dark energy (quantum vacuum energy or scalar fields)? What is the field that drives inflation? Answers to these and other questions will change the picture presented above.

COUPLED MAP LATTICE

Originally introduced in the study of spatiotemporal chaos, the coupled map lattice (CML) can be presented as a dynamical model for the evolution of a spatially extended system in time (Kaneko, 1983). CMLs have been widely used, not only as a tool for the study of spatiotemporal chaos but also for pattern dynamics in physics, chemistry, ecology, biology, brain theory, and information processing.

A CML is a dynamical system with discrete time (map), discrete space (lattice), and a continuous state. It consists of dynamical elements on a lattice, which interact (are coupled) with suitably chosen sets of other elements.

The construction of a CML is carried out as follows. First, choose a (set of) field variable(s) on a lattice. This (set of) variable(s) is on a macroscopic, not a microscopic level. Second, decompose the phenomenon of interest into independent units (e.g., convection, reaction, diffusion, and so on). Third, replace each unit by simple parallel dynamics (procedure) on a lattice, where the dynamics consists of a nonlinear transformation of the field variable at each lattice point and/or a coupling term among suitably chosen neighbors. Finally, carry out each unit dynamics (procedure) successively.

As a simple and widely used example, consider a phenomenon that is created by a locally chaotic process and by diffusion, and choose a suitable lattice model on a coarsegrained level for each process. As the simplest choice, we can adopt some one-dimensional map for chaos, and a discrete Laplacian operator for the diffusion. The former process is given by $x'_n(i) = f(x_n(i))$, where $x_n(i)$ is a variable at time n and lattice site i , ($i = 1, 2, \dots, N$), whereas $x'_n(i)$ is introduced as the intermediate value. The discrete Laplacian operator for diffusion is given by

$$x_{n+1}(i) = (1 - \varepsilon)x'_n(i) + \frac{\varepsilon}{2}\{x'_n(i+1) + x'_n(i-1)\}. \quad (0)$$

Combining the above two processes, the CML is given by

$$x_{n+1}(i) = (1 - \varepsilon)f(x_n(i)) + \frac{\varepsilon}{2}\{f(x_n(i+1)) + f(x_n(i-1))\}. \quad (1)$$

The mapping function $f(x)$ is chosen to depend on the type of local chaos. For example, one can choose the logistic map, $f(x) = rx(1-x)$, as a typical model for chaos. As the map dynamics are well studied, dynamical systems theory can be applied to understand behaviors of the CML.

By adopting different procedures, one can construct models for different types of spatially extended dynamical systems. For problems of phase transition

dynamics, it is useful to adopt a map with bistable fixed points (e.g., $f(x) = \tanh x$) as a local dynamics. The choice of a different type of coupling, as well as the extension to a higher-dimensional space is straightforward. By changing the procedures in the CML, one can easily construct a model for dynamical phenomena in space-time. Examples include spinodal decomposition, crystal growth, boiling, convection, and cloud dynamics, among others.

Universality Classes of the Phenomena

Phenomena found in one CML are often observed in a wide variety of systems, and they form a universality class common to such systems. CMLs thus work as a tool to predict novel phenomenology forming such qualitative universality classes.

In the model of Equation (1), the following phenomena have been discovered: (i) spatial bifurcation and frozen chaos, (ii) spatiotemporal intermittency (STI), (iii) Brownian motion of chaotic defects, and (iv) global traveling wave by local phase slips. These phenomena are observed in a wide variety of systems, including experiments. In particular, STI is now regarded as a universal route to fully developed spatiotemporal chaos. In fully developed spatiotemporal chaos, statistical mechanics theory is developed by taking advantage of the discreteness in spacetime.

If one adopts a two-dimensional lattice system, spiral pattern dynamics are often observed. For example, by taking a local map with an excitable state, the formation of spiral waves is studied, including turbulence due to the break-up of a spiral wave pair. Such a model is studied in relation to the pattern dynamics in reaction-diffusion systems as well as wave propagation in cardiac tissue.

Another straightforward extension is a spatially asymmetric coupling. In an open fluid flow, for example, there is coupling from up-flow to down-flow, instead of the diffusion. The CML $x_{n+1}(i) = (1 - \varepsilon)f(x_n(i)) + \varepsilon f(x_n(i))$ gives a prototype model for such a case. In this open flow system, it is important to distinguish absolute instability from convective instability. If a small perturbation against a reference state grows in a stationary frame, it is called "absolute instability," while if the perturbation grows only in a frame moving with a specific velocity, it is called "convective instability." This convective instability leads to spatial bifurcation from a homogeneous state to down-flow convective chaos.

Globally Coupled Maps with Applications to Biology

An extension of CML to global coupling is interesting, and often important for biological problems. Thus a globally coupled map (GCM) was introduced as a

mean-field-type extension of a CML, written as

$$x_{n+1}(i) = (1 - \varepsilon)f(x_n(i)) + (\varepsilon/N) \sum_{j=1}^N f(x_n(j)). \quad (2)$$

One important notion here is clustering. The elements split into several clusters, within which all the elements oscillate in synchronization. Depending on the numbers of clusters in the GCM, there are phase transitions among a coherent phase, an ordered phase, a partially ordered phase, and a desynchronized phase, as the parameter describing the nonlinearity in $f(x)$ is increased. In the partially ordered phase, there are many attractors with different numbers of clusterings and with a variety of partitions. Dynamically, the system spontaneously switches between ordered states through disordered states, known as chaotic itinerancy. In the desynchronized phase, nontrivial collective motion is observed with some hidden coherence among elements. This demonstrates the existence of macroscopic chaos different from microscopic chaos represented by each map $x_{n+1} = f(x_n)$. This observation may shed new light on the origin of collective behavior by an ensemble of cells, such as an electroencephalogram (EEG) in the brain.

Often, a biological system has both internal dynamics and interactions. Chemical dynamics in a cell includes both intra-cellular reactions associated with gene expressions and cell-cell interactions. Since a CML or GCM is a model for such intra-inter dynamics, the concepts developed in this area will be relevant to biological problems. For example, clustering leads to differentiation of the states of elements. The theory for cell differentiation and robust developmental process may be based on this dynamic differentiation.

COUPLED OSCILLATORS

The simplest coupled oscillator is a pair of linearly coupled harmonic oscillators, which is used as a model for a wide variety of physical systems—including the interactions of musical instruments and tuning forks, lattice vibrations, electrical resonances, and so on—in which energy tunnels back and forth between two sites at a difference (beat) frequency. If there are many elementary oscillators that are nonlinear, coupled systems exhibit more varied nonlinear phenomena. There are two types of coupled nonlinear oscillators: those described by Hamiltonian (energy-conserving) dynamics, and systems in which energy is not conserved. In addition to coupled pendula, examples of the first kind include the Fermi–Pasta–Ulam model and the Toda lattice.

Coupled nonlinear oscillators that do not conserve energy can be viewed as coupled limit cycle oscillators. A limit cycle oscillator (also called a self-sustained oscillator) is described as an attractor in a dissipative dynamical system. A typical dissipative dynamical system that exhibits a limit cycle oscillation is van der Pol's equation

$$\frac{d^2x}{dt^2} - \varepsilon(1 - x^2) \frac{dx}{dt} + \omega^2 x = 0 \quad (1)$$

in which the character of the oscillation varies from sinusoidal and energy-conserving to a strongly dissipative (blocking or relaxation) oscillation through the variation of a parameter (ε) from zero to large values (van der Pol, 1934).

Among the varieties of limit cycle oscillators, the behavior of a quasilinear oscillator (small ε) can be expressed by a sinusoidal wave, $x(t) = A \sin(\omega t + \phi_0)$. The wave shape of a relaxation oscillator (large ε), on the other hand, is composed of alternating fast and slow motions, similar to the spikes and slow recovery motions in a firing neuron, and stick-slip oscillations in frictional motions.

Although the limit cycle oscillation has a certain natural amplitude and frequency, the phase variable, for example, $\phi = \omega t + \phi_0$ for a quasilinear oscillator, is a neutral mode, sensitively perturbed by an external force. If the external force is periodic with a frequency close to the natural frequency of the limit cycle oscillator, the phase of the limit cycle oscillator tends to approach the phase of the external periodic force. If the external force is sufficiently strong, the phase difference $\Delta\phi(t) = \phi(t) - \phi_e(t)$ between the limit cycle oscillator and the external force is fixed. This phenomenon—termed *phase or frequency locking*—occurs more easily when ε is large, the frequency of the limit cycle oscillator is close to that of the external force, and the coupling (K) is large.

Regions in the (ω, ε, K) parameter space where frequency locking is observed are termed “Arnol'd

Figure 1. Frequency distribution $P(\omega)$ (a) in an asynchronous state for $K < K_c$ and (b) in a mutually entrained state for $K > K_c$.

tongues" owing to their peculiar shape. The frequency ratio between the limit cycle and the external force is 1:1 in the above frequency locking. In general, $n:m$ frequency lockings are possible, where n and m are small integers.

For a collection of coupled limit cycle oscillators with slightly different natural frequencies, frequency locking (called mutual entrainment) also occurs, as was first observed by Christiaan Huygens in the 17th century. He found that the motions of pendulum clocks suspended from the same wooden beam come to coincide with each other perfectly. Norbert Wiener analyzed such systems in the 1950s, showing that the power spectrum of the waves should have a peak close to 10 Hz, and he inferred that a similar shape of the power spectra of electroencephalogram (EEG) is due to mutual entrainment in coupled neural oscillators (Wiener, 1958). Buck and Buck reported that rhythmical flashes of South Asian fireflies were mutually synchronized (Buck & Buck, 1976).

Mutual entrainment of coupled limit cycle oscillators has been studied by Winfree (2000) and also by Kuramoto, who considered a coupled phase oscillator model, noting the neutrality of phase variables (Kuramoto, 1984). The simplest model with global coupling has the form

$$\dot{\phi}_i = \omega_i + \frac{K}{N} \sum_{j=1}^N \sin(\phi_j - \phi_i), \quad (2)$$

where ϕ_i and ω_i represent the phase and the natural frequency of the i th oscillator, N is the total number of oscillators, and K is a coupling constant.

For $K < K_c$, the motion of each oscillator is independent and the frequency of the i th oscillator is the same as ω_i . However, for $K > K_c$, collective oscillation appears and a number of oscillators are entrained to the collective oscillation. Figure 1 displays a typical frequency distribution for $K < K_c$ and $K > K_c$. The δ -function peak in the frequency distribution implies mutual entrainment and a depression is seen around the deserved frequency for $K > K_c$.

The Josephson junction is a quantum device composed of two weakly coupled superconductors. With the current bias current below a critical value, the superconducting current flows without a voltage

drop. If the bias is above the critical current, the phase difference (ϕ) between the Josephson junction is not constant in time, and the voltage drop (V) between the Josephson junction equals $\hbar\dot{\phi} = 2$ eV. This is called the AC Josephson effect. Thus the Josephson junction behaves as a kind of limit cycle oscillator above the critical current. If microwaves with frequency ω_0 are applied to the Josephson junction, $n:1$ frequency locking occurs, and the voltage becomes $V = n\hbar\omega_0/2e$. With N Josephson junctions coupled in series, the total voltage across the array is given by $V = Nn\hbar\omega_0/2e$. Such series arrays are currently used to establish the international standard of voltage (See **Josephson junction arrays**).

COUPLED SYSTEMS OF PARTIAL DIFFERENTIAL EQUATIONS

Coupled systems of nonlinear partial differential equations (PDEs) are often derived to simplify complicated systems of governing equations in theoretical and applied sciences (Engelbrecht et al., 1988). Nonlinear electromagnetic theory, fluid dynamics, and systems in general relativity are difficult computational problems even with the help of numerical algorithms and the latest computer technologies. Using additional assumptions on properties of nonlinear wave processes in physical systems, however, one can derive coupled systems of nonlinear PDEs from the original governing equations, which simplify the analysis.

The main effects of nonlinear waves (such as nonlinearity, dispersion, diffraction, diffusion, damping and driven forces, and resonances) can be described with coupled nonlinear PDEs. Such systems may exhibit simple solutions such as traveling solitary waves and periodic waves, and some can be solved with the inverse scattering transform methods. Coupled systems comprise various combinations of nonlinear evolution equations that describe long solitary waves (Korteweg–de Vries and Boussinesq equations), envelope waves (nonlinear Schrödinger equations), kinks

and breathers (sine-Gordon equations), and traveling fronts and pulses (reaction-diffusion systems). Here, we present a few examples.

Long surface water waves occur in oceans, seas, and lakes. The tsunami wave (Bryant, 2001) is an example of a nonlinear surface wave that arises following underwater earthquakes or underwater volcano eruptions and may reach heights of 20–30 m as it comes ashore. Because tsunamis are as long as tens and hundreds of kilometers, the ocean can be considered as shallow for such waves. This shallow-water approximation reduces the Euler equations for water waves to the Boussinesq system of coupled PDEs (Whitham, 1974):

$$\begin{aligned} u_t + uu_x + g\eta_x - (h^3/3)u_{txx} &= 0, \\ \eta_t + hu_x + \eta u_x + u\eta_x &= 0, \end{aligned}$$

where $\eta = \eta(x, t)$ is the wave surface elevation, $u = u(x, t)$ is the horizontal velocity, h is the water depth, and g is the gravitational acceleration.

The linear Boussinesq equation takes the form of the wave equation: $\eta_{tt} - c^2\eta_{xx} = 0$, which exhibits a two-wave solution $\eta = f(x - ct) + g(x + ct)$, where $f(x)$, $g(x)$ are arbitrary functions and $c = \sqrt{gh}$ is the wave speed. When the two waves are separated in space, small nonlinearity and dispersion are captured in the unidirectional Korteweg–de Vries (KdV) equation (Johnson, 1997):

$$\eta_t + c \left(1 + \frac{3\eta}{2h} \right) \eta_x + \frac{ch^2}{6} \eta_{xxx} = 0.$$

Different modes of long weakly nonlinear waves may travel with the same speed, exchanging energy by means of wave resonances. Because ocean water is stratified in density and shear flow, gravity waves can propagate along internal interfaces of the ocean stratification. Resonant interaction of internal wave modes in stratified shear flows is described by the system of coupled KdV equations (Grimshaw, 2001):

$$u_t + Au_x + B(u)u_x + Cu_{xxx} = 0,$$

where A , $B(u)$, C are matrices and $u = u(x, t)$ is the vector for amplitudes of different internal wave modes.

Optical pulses may consist of electromagnetic waves in optical fibers, waveguides, and transmission lines. The propagation of optical pulses due to a balance between nonlinearity and dispersion is based on the paraxial approximation of the Maxwell equations with nonlinear refractive indices. This perturbation technique results in the nonlinear Schrödinger (NLS) equation (Newell & Moloney, 1992):

$$i\psi_t + \frac{1}{2}\omega''(k_0)\psi_{xx} + \gamma(k_0)|\psi|^2\psi = 0,$$

where $\psi = \psi(x, t)$ is the envelope amplitude of a wave packet with the carrier wave number k_0 . Depending

on the relative signs of the dispersion coefficient $\omega''(k_0)$ and the nonlinearity coefficient $\gamma(k_0)$, wave perturbations are focused or defocused in the time evolution of the NLS equation. Interactions between waves with two orientations of polarization (ψ_y and ψ_z with propagation in the x -direction) can be represented in a normalized form as

$$\begin{aligned} i\psi_{y,t} + \psi_{y,xx} + 2(|\psi_y|^2 + |\psi_z|^2)\psi_y &= 0 \\ i\psi_{z,t} + \psi_{z,xx} + 2(|\psi_y|^2 + |\psi_z|^2)\psi_z &= 0. \end{aligned}$$

These are a pair of coupled NLS equations that are integrable by the inverse scattering transform method and display vector solitons (Manakov, 1974). Under collisions, the polarization vectors of two vector solitons change.

In wavelength-division-multiplexing optical systems, optical signals are transmitted through parallel channels at different carrier wave numbers (up to 40 channels in latest communication lines). Incoherent interaction of optical pulses at nonresonant frequencies is described by the system of coupled NLS equations (Akhmediev & Ankiewicz, 1997):

$$i\psi_t + D\psi_{xx} + E(|\psi|^2)\psi = 0,$$

where D and $E(|\psi|^2)$ are matrices and $\psi = \psi(x, t)$ is the vector for optical pulses in different channels. If the coupling between optical pulses is coherent (as in birefringent fibers, waveguide couplers, phase mixers, and resonant optical materials), the system of coupled NLS equations takes a general form:

$$i\psi_t + A\psi + iB\psi_x + iC(\psi)\psi_x + D\psi_{xx} + E(\psi)\psi = 0.$$

The coupled NLS equations describe phase-matching resonance in quadratic χ^2 materials, gap solitons in periodic photonic gratings under Bragg resonance, Alfvén waves in plasmas, and other applications (Newell & Moloney, 1992).

In conservative nonlinear systems, wave dynamics of small amplitudes occur typically in the neighborhood of local minima of potential energy. Wave oscillations in the system of nonlinear massive pendulums are described by the Frenkel–Kontorova dislocation model. In a continuous approximation, the Frenkel–Kontorova lattice model reduces to the sine-Gordon (SG) equation (Braun & Kivshar, 1998):

$$\varphi_{tt} - c^2\varphi_{xx} + \sin \varphi = 0,$$

where φ is the angle between a pendulum and the vertical axis in a mechanical model. The nonlinear pendulums swing on a rigid rod under the gravity force and couple to each other with elastic springs. More complicated models of molecular crystals and ferromagnetics in solid state mechanics, stacked Josephson contacts in superconductivity, and strings in

the general relativity theory are formulated as coupled systems of sine-Gordon equations (Mauguin, 1999). The coupled Klein-Gordon equations take the form

$$\varphi_{tt} - C\varphi_{xx} + f(\varphi) = 0,$$

where C is a positive-definite matrix and $f(\varphi)$ is the nonlinear vector function of components of the vector $\varphi = \varphi(x, t)$.

In more general systems, the energy of a nonlinear wave changes in time due to active and dissipative forces. The simplest system of this type is the nonlinear heat equation, which models the flame propagation (Zeldovich et al., 1985):

$$u_t = Du_{xx} + f(u),$$

where $u = u(x, t)$ is the temperature and D is the diffusivity constant. A complex form of the nonlinear heat equation (known as the Ginzburg-Landau equation) is derived for the amplitude of the most unstable wave mode (Newell & Moloney, 1992).

Active and dissipative systems include typically pairs of coupled activators and inhibitors. Coupled activator-inhibitor equations, known as the reaction-diffusion systems, are derived from the governing equations of thermodynamics in the form (Remoissenet, 1999):

$$u_t = Cu_x + Du_{xx} + f(u),$$

where C and D are matrices, and $f(u)$ is a nonlinear vector function of components of the vector $u = u(x, t)$. Reaction-diffusion systems exhibit static, traveling, and pulsating nonlinear wave structures such as fronts and impulses. Coupled reaction-diffusion systems include the FitzHugh-Nagumo and Hodgkin-Huxley equations for nerve impulses, ephaptic coupling among nerve impulses, and models of the global dynamics of heart.

CRITICAL PHENOMENA

The term *critical phenomenon* is used synonymously with "phase transition," which involves a change of one system phase to another and occurs at a characteristic temperature (called a transition temperature or a critical temperature: T_c). There are several different kinds of phase transitions such as melting, vaporization, and sublimation, as well as solid-solid, conducting-superconducting, and fluid-superfluid transitions. In systems undergoing phase transitions, an emergence of long-range order is seen in which the value of a physical quantity at one arbitrary point in the system is correlated with its value at another point a long distance away.

A classification scheme of phase transitions which remains the most popular was originally proposed by Paul Ehrenfest. According to this scheme, a transition for which the first derivative of the free energy with respect to temperature is discontinuous is called a first-order phase transition; thus, the heat capacity, C_p , at a first-order transition is infinite. A second-order phase transition is one in which the first derivative of the thermodynamic potential with respect to temperature is continuous, but its second derivative is discontinuous, so the heat capacity is discontinuous but not infinite at the transition. Near a second-order phase transition (due to the reduction of rigidity of the system), critical fluctuations dominate as their amplitudes diverge.

A useful concept in analyzing phase transitions is that of a critical exponent. In general, if a physical quantity $Q(T)$ either diverges or tends to a constant value (see Figure 1) as T tends to T_c , it can be characterized by defining the reduced temperature ε as

$$\varepsilon \equiv \frac{T - T_c}{T_c}. \quad (1)$$

The associated critical exponent is

$$\mu = \lim_{\varepsilon \rightarrow 0} \frac{\ln Q(\varepsilon)}{\ln \varepsilon}. \quad (2)$$

The most important critical exponents are denoted as α , β , γ , δ , ν , and η and describe the specific heat, order parameter, isothermal susceptibility, response to an external field, the correlation length, and the pair correlation function, respectively. (See Table 1 where

Figure 1. The four generic behaviors near criticality.

the primed exponents are introduced for temperatures below the critical temperature while the unprimed exponents are valid above the critical temperature.)

The mean field approximation (Landau theory) describes the physics of phase transitions well except in the immediate vicinity of the critical point where order parameter fluctuations are large. It is assumed that close to T_c , the free energy F can be expanded in a Taylor series of the order parameter ψ . Introducing the reduced temperature ε as a control parameter, the simplest such expansion is (see Figure 2)

$$F(T, V, \psi) = F_0 + a\varepsilon\psi^2 + A_4\psi^4, \quad (3)$$

Figure 2. A prototype of second-order phase transitions according to Landau.

where $a > 0$ and $A_4 > 0$. Solving the equilibrium conditions for ψ yields $\psi = 0$ for $\varepsilon > 0$ and

$$\psi = \pm \left(-\frac{a\varepsilon}{2A_4} \right)^{1/2} \quad \text{for } \varepsilon < 0, \quad (4)$$

thus $\beta = 0.5$ is obtained. Calculating the entropy

$$S = \frac{\partial F}{\partial T} = S_0 + \frac{a^2}{2A_4 T_c} \varepsilon \quad \varepsilon \leq 0, \quad (5)$$

where for $\varepsilon > 0$, $S = S_0$ is the entropy of the disordered phase, which gives the specific heat as

$$C_v = T \frac{\partial S}{\partial T} = C_0 + \frac{a^2}{2A_4 T_c} T \quad \varepsilon \leq 0, \quad (6)$$

where for $\varepsilon > 0$, $C_v = C_0$ is the specific heat of the disordered phase. Hence, a discontinuity occurs at T_c (see Figure 3).

$$\Delta C = \frac{a^2}{2A_4 T_c}. \quad (7)$$

Thus, $\alpha = 0$.

Including in F an external field h coupled to ψ

$$F = F_0 + a\varepsilon\psi^2 + A_4\psi^4 - h\psi \quad (8)$$

Exponent	Definition (liquid-vapor) Specific heat at constant volume	Definition (magnetic) Specific heat at constant H
α'	$C_v \sim (-\varepsilon)^{-\alpha'}$	$C_H \sim (-\varepsilon)^{-\alpha'}$
α	$C_v \sim \varepsilon^{-\alpha}$	$C_H \sim \varepsilon^{-\alpha}$
	Density difference	Magnetization
β	$\rho_L - \rho_G \sim (-\varepsilon)^\beta$	$M \sim (-\varepsilon)^\beta$
	Isothermal compressibility	Isothermal susceptibility
γ'	$\kappa_T \sim (-\varepsilon)^{-\gamma'}$	$\chi T \sim -\varepsilon^{-\gamma'}$
γ	$\kappa_T \sim \varepsilon^{-\gamma}$	$\chi T \sim \varepsilon^{-\gamma}$
	Pressure-density critical isotherm	Magnetic field-magnetization
δ	$P - P_c \sim \rho_L - \rho_G ^\delta$ ($T = T_c$)	$H \sim M ^\delta$ ($T = T_c$)
	Correlation length	Correlation length
ν'	$\xi \sim (-\varepsilon)^{-\nu'}$	$\xi \sim -\varepsilon^{-\nu'}$
ν	$\xi \sim \varepsilon^{-\nu}$	$\xi \sim \varepsilon^{-\nu}$
	Density-density pair correlation	Spin-spin pair correlation
η	$\Gamma(r) \sim r ^{-(d-2+\eta)}$	$\Gamma(r) \sim r ^{-(d-2+\eta)}$

Table 1. The definitions of critical exponents for liquid-vapor and magnetic systems. [The primed (unprimed) exponents are for temperatures below (above) T_c .]

Figure 3. Plots of $S(T)$ and $C_v(T)$ in the Landau model of a second-order phase transition.

and minimizing F with respect to ψ yields an equation of state of the form

$$h = 2\psi[a\varepsilon + 2A_4\psi^2]. \quad (9)$$

Because the susceptibility $\chi \equiv \partial\psi/\partial h$, we find

$$\chi = [2a\varepsilon + 12A_4\psi^2]^{-1}. \quad (10)$$

As $\psi \rightarrow 0$ as $T \rightarrow T_c$, the third exponent is $\gamma = 1$. At $T = T_c$, the equation of state (9) simplifies to:

$$h \cong 4A_4\psi^3, \quad (11)$$

and hence $\psi \sim h^{1/3}$ giving $\delta = 3$. The quartic expansion in the Landau model invariably leads to the

classical critical exponents: $\alpha = 0$, $\beta = 0.5$, $\gamma = 1$, and $\delta = 3$.

While the Landau theory cannot describe spatial fluctuations, following Ginzburg and Landau's proposal, it can be extended to consider the free energy to be a functional:

$$F(\psi(\vec{r}), T) = \int d^3\mathbf{r} [A_2\psi^2 + A_4\psi^4 - h\psi + D(\nabla\psi)^2] \quad (12)$$

where D describes the energy due to spatial inhomogeneities. Applying a variational principle to F results in a nonlinear Klein-Gordon equation for the order parameter

$$h = 2A_2\psi + 4A_4\psi^3 - 2D\nabla^2\psi. \quad (13)$$

A linearized solution of Equation (13) in spherical coordinates is

$$\psi = \frac{h_0}{4\pi D} \frac{e^{-r/\xi}}{r}, \quad (14)$$

where $\xi \sim A_2^{-1/2}$ is the correlation length that diverges as $T \rightarrow T_c$ so that the critical exponent $\nu = 0.5$. Fourier transforming the order parameter according to

$$\psi(\vec{r}) \equiv L^{-d/2} \sum_{k < k_0} \psi_k e^{i\vec{k} \cdot \vec{r}}, \quad (15)$$

where d is the spatial dimensionality and the cutoff wavelength $k_0 = \Lambda^{-1}$ corresponds to the smallest periodicity, F becomes (for $h = 0$)

$$F = \sum_{k < k_0} |\psi_k|^2 (A_2 + Dk^2) + L^{-d} \sum_{k, k', k'' < k_0} A_4 \psi_k^* \psi_{k'}^* \psi_{k''} \psi_{k+k'-k''} \quad (16)$$

Ignoring mode-mode coupling provides the basis for a Gaussian approximation, where

$$F \cong \sum_{k < k_0} |\psi_k|^2 (A_2 + Dk^2). \quad (17)$$

The Fourier transform of the correlation function is found as

$$\begin{aligned} \Gamma(k) &= L^{-d} \int e^{-i\vec{k}(\vec{r}-\vec{r}')} \langle \psi(\vec{r}) \psi(\vec{r}') \rangle d\vec{r} d\vec{r}' \\ &= \langle |\psi_k|^2 \rangle \cong \frac{n}{2} (A_2 + Dk^2)^{-1} \end{aligned} \quad (18)$$

Therefore, as $T \rightarrow T_c$, we find that $\Gamma(k) \sim k^{\eta-2}$ with $\eta=0$ in the Gaussian approximation and also $\Gamma(r) \sim r^{-(d-2)}$. Furthermore, the Gaussian approximation introduces a new value of the specific heat critical exponent $\alpha = 2 - d/2$.

D

DAMPED-DRIVEN ANHARMONIC OSCILLATOR

Many problems in engineering and the applied sciences are modeled by low-dimensional forced oscillators. Examples include vibrating mechanical and structural engineering systems (beams, bridges), marine systems (ships, oil platforms), electronic circuits and devices (Josephson junctions), as well as biological oscillators. While the linear behavior of such systems has long been well understood, the potential dynamics of nonlinear oscillators is far more complex and many open problems remain.

Damped Nonlinear Pendulum

Let us consider a mathematical pendulum and denote with θ the angular displacement of the pendulum from the equilibrium (hanging down) position. The equation of motion for the oscillations of a damped nonlinear pendulum of unitary mass is

$$\frac{d^2\theta}{dt^2} + \eta \frac{d\theta}{dt} + \frac{g}{l} \sin(\theta) = 0, \quad (1)$$

where l is the length of the pendulum and g is the gravitational acceleration. This equation expresses Newton's second law with the terms on the left-hand side, respectively, representing acceleration, damping, and gravitation. Equation (1) may be rewritten as two first-order equations:

$$\begin{cases} \dot{\theta} = \omega, \\ \dot{\omega} = -\eta\omega - \frac{g}{l} \sin(\theta), \end{cases} \quad (2)$$

where ω denotes the angular velocity. Then, one can use (θ, ω) as phase space coordinates.

Fixed points: The dynamics of the nonlinear pendulum can be analyzed as trajectories in the phase space. The rest position $\theta = \omega = 0$ is called a *fixed point*. It is easy to see that almost all phase space trajectories spiral into the fixed point at $(0, 0)$. This is a linearly

stable fixed point, since if a small perturbation is made from the fixed point, the perturbation decays in time (exponentially for small enough perturbations). There is a second fixed point at $(\pi, 0)$ corresponding to the pendulum pointing vertically up. The fixed point at $(\pi, 0)$ is linearly unstable because a small perturbation from this fixed point grows exponentially. Only very carefully tuned initial conditions will lead to a trajectory ending on the unstable fixed point, and almost all perturbations to the initial condition will lead to a trajectory that may approach close to the unstable fixed point, but eventually spirals into the stable fixed point. The $(0, 0)$ fixed point is attracting, and in this case the basin of attraction, that is, the set of initial conditions leading to trajectories that approach the fixed point, is the whole phase space except for a set of zero measure.

An example of a trajectory of system (2) converging towards the stable fixed point at $(0, 0)$ is shown in Figure 1.

The Periodically Driven Damped Pendulum

Let us now consider the nonlinear damped pendulum of Equation (1) when a harmonic driving force is applied. The equation of motion for the oscillations of a damped, sinusoidally driven nonlinear pendulum is

$$\frac{d^2\theta}{dt^2} + \gamma \frac{d\theta}{dt} + \sin(\theta) = A_D \cos(\omega_D t), \quad (3)$$

where A_D is the forcing amplitude and the angular velocity of the forcing, ω_D , may be different from the natural frequency of the pendulum. Note, with respect to Equation (1), that the time variable has been rescaled so that the period of small oscillations of the undamped and undriven pendulum is unity, and the (scaled) dissipation coefficient is now denoted by γ . Physically, the situation corresponds to driving the pendulum, feeding in energy to resupply the energy dissipated.

Small-Amplitude Oscillations

For small driving amplitudes, A_D , and assuming a small initial condition, one can approximate $\sin \theta \approx \theta$ and

Figure 1. Typical trajectory for the nonlinear pendulum of Equation (2). All initial conditions lead to an orbit spiraling into the fixed point at $(0, 0)$.

Figure 2. If small driving is turned on ($A_D = 0.1$), the steady-state solution is a stable limit cycle. Note that, for simplicity, the transient dynamics are not shown.

solve Equation (3) analytically:

$$\theta = \frac{A_D}{\sqrt{(1 - \omega_D^2)^2 + \gamma^2 \omega_D^2}} \cos(\omega_D t + \Phi) + A_0 e^{-\gamma t/2} \cos(\omega t + \varphi_0), \quad (4)$$

where

$$\tan \Phi = -\frac{\gamma \omega_D}{(1 - \omega_D^2)}, \quad \omega = \sqrt{1 - \frac{\gamma^2}{4}}, \quad \gamma < 2 \quad (5)$$

while the constants A_0 and φ_0 depend upon the initial conditions (θ_0, ω_0) , that is, for $t = 0$.

Equation (4) describes the resonant response (the first term) oscillating at the applied frequency, together with decaying free oscillations (the second term), depending on the initial conditions. This kind of solution is called an attracting *limit cycle*.

A typical limit cycle at this small amplitude, for $A_D = 0.1$, is shown in Figure 2 and is seen to be close to circular. From now on, although the transient may be

Figure 3. Large-amplitude limit cycle, for $A_D = 0.9$.

Figure 4. Chaotic attractor, for driving amplitude $A_D = 1.15$.

quite complicated, only the asymptotic behavior, that is, the behavior of the attractors will be considered.

Large-Amplitude Solutions

What happens for large driving amplitudes? Here, there are no analytic solutions, and one must proceed numerically. To gain some intuition it is more convenient to view the dynamics in the phase space. To this end, Equation (3) may be converted to autonomous form by using three variables, as follows:

$$\begin{cases} \dot{\theta} = \omega, \\ \dot{\omega} = -\gamma \omega - \sin(\theta) + A_D \cos(\theta_D), \\ \dot{\theta}_D = \omega_D, \end{cases} \quad (6)$$

where the phase of the driving, θ_D , has been introduced.

If one increases the driving strength to $A_D = 0.9$, a large-amplitude limit cycle is observed, as shown in Figure 3. This limit cycle bifurcates for increasing values of the driving strength according to the well-known period-doubling route to chaos, leading to a chaotic attractor for $A_D = 1.09$.

Then, increasing the driving to $A_D = 1.15$ results in an even more irregular chaotic behavior, as illustrated in Figure 4. But, perhaps at first sight surprisingly, increasing the driving further, for example, to $A_D = 1.35$ gives periodic motion again. In this case, though, there is a drift along with the oscillation—the

pendulum is oscillating but also consistently rotating all the way around.

In summary, numerical simulations show that both periodic and chaotic solutions of the driven damped pendulum are possible, depending on the particular choice of the system parameters. Chaos may indeed occur since the driven pendulum equation is equivalent to a three-dimensional nonlinear autonomous system. Note the contrast with linear theory, where a damped system driven periodically *must* eventually respond periodically.

DARBOUX TRANSFORMATION

From a historical point of view, the Darboux transformation is the specialization of a more general result due to Théodore Moutard. The prior result is of application in the classical theory of surfaces (Darboux, 1887–96) and takes the following form.

Let $\phi_0(x, y)$ be any particular integral of the hyperbolic partial differential equation

$$\phi_{xy} + q(x, y)\phi = 0, \quad (1)$$

$q(x, y)$ being a given function. We may rewrite this equation in the form

$$(D_x^+ D_y^- + D_y^+ D_x^-)\phi = 0, \quad (2)$$

where the D_s are differential operators, $D_u^\pm = \partial_u \pm \phi_0^{-1}\phi_{0u}$. Now let $\psi(x, y)$ and $\phi(x, y)$ be functions satisfying the pair of first-order partial differential equations

$$\begin{aligned} D_x^- \phi &= -D_x^+ \psi, \\ D_y^- \phi &= D_y^+ \psi, \end{aligned} \quad (3)$$

then (1) is equivalent to the identity $[D_x^+, D_y^+]\psi = 0$. Alternatively, the identity $[D_x^-, D_y^-]\phi = 0$ yields an equation for ψ , namely,

$$\psi_{xy} + p(x, y)\psi = 0, \quad (4)$$

where $p(x, y) = q(x, y) + 2(\ln \phi_0)_{xy}$. The class of equations of form (1) is thus covariant under maps $\mu_{\phi_0}: (\phi, q) \mapsto (\psi, p)$.

The map μ_{ϕ_0} is the *Moutard* transformation and its value lies in its relating, and generating, hyperbolic equations integrable in finite terms (Darboux, 1887–96).

Darboux (1882) specialized this result to the case where (1) carries a symmetry, that is, where $q(x, y) = Q(x + y)$ is a function of $x + y$ only. Putting $z = x + y$, $\bar{z} = x - y$ and applying the standard technique of separation of variables leads to $\phi(x, y) = \exp(\lambda\bar{z})\Phi(z, \lambda)$ and the equation for Φ ,

$$\Phi_{zz} + Q(z)\Phi = \lambda^2\Phi. \quad (5)$$

Given a solution Φ_0 to this equation with $\lambda = \lambda_0$, there is a corresponding $\phi_0(x, y) = \exp(\lambda_0\bar{z})\Phi_0(z, \lambda_0)$ and after a simple, constant rescaling of Φ , Equations (3) become

$$\begin{aligned} \Psi &= (\partial_z - \Phi_0^{-1}\Phi_{0z})\Phi, \\ (\lambda^2 - \lambda_0^2)\Phi &= (\partial_z + \Phi_0^{-1}\Phi_{0z})\Psi \end{aligned} \quad (6)$$

and Equation (5) becomes

$$\Psi_{zz} + P(z)\Psi = \lambda^2\Psi. \quad (7)$$

Here $P(z) = Q(z) + 2(\ln \Phi_0)_{zz}$.

The map $\delta_{\lambda_0}: (\Phi, Q) \mapsto (\Psi, P)$ is the *Darboux* transformation (DT). Note that it creates from the Φ equation one member of a family of equations depending on the free parameter λ_0 .

Starting with $Q=0$ and a specific choice λ_0 for λ , we may take $\Phi_0 = c_1 \cosh \lambda_0(z + c_2)$. Then $P(z) = 2\lambda_0^2 \operatorname{sech}^2 \lambda_0(z + c_2)$ and so, from the trivial (“vacuum”) potential, the DT has generated a family of potential barriers involving the chosen λ_0 and a parameter of translation, c_2 , in the z -direction.

The linear PDE (5) plays a crucial role in the Inverse Scattering Transform (IST). We suppose the potential Q to depend upon an additional parameter t (“time”): $Q = Q(z, t)$. The pair of linear PDE (Lax pair),

$$L_Q \Phi = \lambda^2 \Phi, \quad (8)$$

$$M_Q \Phi = \partial_t \Phi, \quad (9)$$

where $L_Q = \partial_z^2 + Q$ and $M_Q = 4\partial_z^3 + 6Q\partial_z + 3Q_z$, is integrable in the Cauchy sense provided Q satisfies the nonlinear PDE

$$Q_t = Q_{zzz} + 6QQ_z, \quad (10)$$

namely, the Korteweg–de Vries (KdV) equation. This follows from the operator relation (Frobenius condition)

$$L_Q t = [M_Q, L_Q] \equiv M_Q L_Q - L_Q M_Q. \quad (11)$$

The DT, $\Psi = \mathcal{D}\Phi$ for $\mathcal{D} = \partial_z + \alpha$, $\alpha = -\Phi_0^{-1}\Phi_{0z}$, is seen to play the role of an intertwining operator:

$$\mathcal{D}L_Q = L_P \mathcal{D}, \quad (12)$$

and

$$\partial_t \Psi = M_P \Psi + \{\alpha_t + \mathcal{D}M_Q - M_P \mathcal{D}\}\Phi. \quad (13)$$

Some calculation shows that the bracketed term is vanishing and we have the Lax pair

$$L_P \Psi = \lambda^2 \Psi, \quad (14)$$

$$M_P \Psi = \partial_t \Psi, \quad (15)$$

in the DT transformed variables Ψ and P . Consequently, the transformed potential P will also satisfy the KdV equation (10).

Returning now to the simple example above, Φ_0 will satisfy Equation (9) with $Q = 0$, namely $\Phi_{0t} = 4\Phi_{0zzz}$, so that $\Phi_0 = c_1 \cosh(\lambda_0 z + 4\lambda_0^3 t + c_3)$ and the DT generates the traveling wave (1-soliton) solution to the KdV,

$$P = 2\lambda_0^2 \operatorname{sech}^2(\lambda_0 z + 4\lambda_0^3 t + c_3). \quad (16)$$

Imagine now that we wish to form a sequence of DTs. Starting with (5), we make a choice Φ_0 , λ_0 to form (7) via (6). Now for (7) we choose Ψ_1 , λ_1 and use

$$\Theta = (\partial_z - \Psi_1^{-1}\Psi_{1z})\Psi$$

to generate Θ , satisfying

$$\Theta_{zz} + R(z)\Theta = \lambda^2 \Theta,$$

where $R = P + 2(\ln \Psi_1)_{zz}$. But since Ψ_1 satisfies (6) with $\lambda = \lambda_1$, it can itself be constructed as

$$\Psi_1 = \Phi_{1z} - \Phi_0^{-1}\Phi_{0z}\Phi_1,$$

where Φ_1 satisfies (5) with $\lambda = \lambda_1$. Then simple algebra yields formulae for Θ and R :

$$\Theta = \begin{vmatrix} \Phi_0 & \Phi_1 \\ \Phi_{0z} & \Phi_{1z} \end{vmatrix}^{-1} \begin{vmatrix} \Phi_0 & \Phi_1 & \Phi \\ \Phi_{0z} & \Phi_{1z} & \Phi_z \\ \Phi_{0zz} & \Phi_{1zz} & \Phi_{zz} \end{vmatrix}, \quad (17)$$

$$R = Q + 2 \ln \left(\begin{vmatrix} \Phi_0 & \Phi_1 \\ \Phi_{0z} & \Phi_{1z} \end{vmatrix} \right)_{zz}. \quad (18)$$

From the symmetry of these formulae under interchange of λ_0 and λ_1 , it follows that the order of composition of DTs is immaterial. The fundamental result of Crum (1955) is that, starting with $n + 1$ pairs

(Φ_i, λ_i) , $i = 0, \dots, n$, associated with (5) one obtains the n -fold DT:

$$\begin{aligned} \delta_0 \dots \delta_n(\Phi, Q) &= (W^{-1}(\Phi_0, \dots, \Phi_n) \\ &\quad \times W(\Phi_0, \dots, \Phi_n, \Phi), Q \\ &\quad + 2 \ln W(\Phi_0, \dots, \Phi_n)_{zz}), \end{aligned}$$

where W denotes the Wronskian function of its arguments.

This result, when applied to a set of n single soliton solutions of the KdV, yields an explicit n -soliton solution.

Generally speaking, a transformation of dependent variables that carries solutions of one DE to solutions of another is termed a *Bäcklund transformation* (BT). The term *Darboux transformation* refers to the special case of linear equations. We have described above a DT for a Lax pair that gives rise to a BT for the KdV equation.

For DTs of higher order, ordinary linear differential equations have been developed. For such results the intertwining property can be related to the factorization of differential operators, an approach to solvable Schrödinger potentials pioneered in quantum mechanics. This naturally leads to their algebraic formulation in terms of $\mathcal{D}$ -modules. Moutard (sometimes called the Binary DT) and Darboux transformations have also been generalized to higher dimensions and utilized for solving associated analogues of the KdV with three independent variables, the Kadomtsev–Petviashvili, Novikov–Veselov, and Davey–Stewartson equations, to name but three.

The double logarithmic derivative occurring in the expression of the DT transformed potentials is of fundamental importance in the bilinear theory of soliton equations originally due to Hirota.

In the Hamiltonian theory of soliton equations the DT is seen to play the role of a canonical transformation.

A comparatively recent application of DTs has been in the theory of integrable systems with discrete variables, that is, systems defined on lattices (Antoniu & Lambert, 2000).

Finally, it should be remarked that the geometrical insights of Gaston Darboux, Luigi Bianchi, and their contemporaries are being rediscovered and developed within the modern theory of integrable systems and that Darboux and Moutard transformations are playing a key role in this resurgence (Rogers & Schief, 2002).

There are a number of monographs where further details about DTs and BTs may be found, for example, Calogero & Degasperis (1982); Konopelchenko (1987); Matveev & Salle (1991); Rogers & Shadwick (1982). For more recent reviews of work in this area see Coley (2001).

DAVEY–STEWARTSON EQUATION

See **Multidimensional solitons**

DAVYDOV SOLITON

In 1972, a meeting was convened in order to search for the general principles that underlie biological processes such as muscle contraction, active transport, enzyme catalysis, and oxidative phosphorylation (Green, 1974). One of the main questions asked was whether there was a crisis in bioenergetics. While some participants disagreed that a crisis existed, others proposed solutions to the crisis. One solution was the “conformon” of Green and Ji, defined as the free energy associated with a localized conformational strain, which was to store and transport energy (Green, 1974, pp. 419–437). McClare’s paper, on the other hand, suggested that vibrational excited states and resonant energy transfer constitute a fundamental step in energy transduction in biological systems (Green, 1974, pp. 74–97). The main objection to McClare’s proposal was that the lifetime of vibrational excited states, thought to be in the subpicosecond time range, was considered too short for these states to be useful. Alexander Davydov’s model, proposed in connection with a mechanism for muscle contraction (Davydov, 1982), aimed to answer this objection.

The Davydov Model

The Davydov model describes energy transfer in the hydrogen-bonded spines that stabilize protein

α -helices:

The idea is that the energy liberated in the hydrolysis of adenosine triphosphate (ATP) creates up to two quanta of amide-I, an excited vibrational state in the peptide group that is essentially a stretching vibration in the C=O bond (Davydov, 1982). This vibration excitation propagates from one group to the next because of the dipole-dipole interaction between the groups. But it also interacts with the neighboring hydrogen bonds, leading to a deformation of the lattice and a lower energy state. This new state, which is constituted by an amide-I excitation and its associated hydrogen bond distortion, is the Davydov soliton. Structurally, the Davydov soliton is, in fact, a subtle local conformational change of the α -helix, similar to the conformon.

Davydov’s Hamiltonian has three parts:

$$\hat{H} = \hat{H}_{\text{ex}} + \hat{H}_{\text{int}} + \hat{H}_{\text{ph}}, \quad (1)$$

where $\hat{H}_{\text{ex}}$, the exciton Hamiltonian, describes the transfer of an amide-I excitation between adjacent sites

$$\hat{H}_{\text{ex}} = -V \sum_{n=1}^N [(\hat{a}_n^\dagger \hat{a}_{n-1} + \hat{a}_n^\dagger \hat{a}_{n+1})], \quad (2)$$

– V being the dipole-dipole interaction energy between neighboring sites, $\hat{a}_n^\dagger (\hat{a}_n)$ the creation (annihilation) operator for a quantum quasiparticle (the amide-I excitation) at site n , and N being the number of sites (the peptide groups) in the lattice; $\hat{H}_{\text{ph}}$, the phonon Hamiltonian, describes the vibrations of the peptide groups n in the one-dimensional chain:

$$\hat{H}_{\text{ph}} = \frac{1}{2} \sum_{n=1}^N \left[\kappa (\hat{u}_n - \hat{u}_{n-1})^2 + \frac{\hat{P}_n^2}{M} \right], \quad (3)$$

$\hat{u}_n$ being the displacement operator from the equilibrium position of site n , $\hat{P}_n$ the momentum operator of site n , M the mass of each site, and κ the elasticity constant of the lattice; $\hat{H}_{\text{int}}$, the interaction Hamiltonian, describes the interaction of amide-I excitation with the motions of the lattice sites:

$$\hat{H}_{\text{int}} = \chi \sum_{n=1}^N [(\hat{u}_{n+1} - \hat{u}_{n-1}) \hat{a}_n^\dagger \hat{a}_n], \quad (4)$$

χ being an anharmonic parameter arising from the coupling between the vibrational excitation and the lattice displacements.

Davydov’s Hamiltonian (Equations (1)–(4)) is formally similar to the Holstein Hamiltonian for the interaction of electrons with a polarizable lattice. The

difference is that while Davydov's Hamiltonian couples quantum particles to acoustic phonons, the Holstein Hamiltonian couples quantum particles to optical phonons.

In Equations (1–4) both the excitation and the lattice are treated quantum mechanically. Exact wavefunctions for the system are yet to be determined in this approximation, and different solutions have been proposed in the literature (see references in Scott, 1992; Cruzeiro-Hansson & Takeno, 1997). On the other hand, when the lattice is treated classically, an approximation that has been called mixed quantum-classical (Cruzeiro-Hansson & Takeno, 1997), it is possible to determine exact wave functions. They are

$$|\psi(t)\rangle = \sum_{i=1}^N \varphi_i(\{u_m\}, \{p_m\}, t) \hat{a}_i^\dagger |0\rangle, \quad (5)$$

where the dependence of the probability amplitude for an excitation at site i on the displacements and momenta of all the sites is not specified *a priori*. The equations of motion for the quantum variables are derived from Schrödinger's equation, while the equations of motion for the classical variables are derived from Hamilton's equations. For a one-quantum state they are

$$i\hbar \frac{d\varphi_n}{dt} = -V(\varphi_{n-1} + \varphi_{n+1}) + \chi(u_{n+1} - u_{n-1})\varphi_n, \quad (6)$$

$$M \frac{d^2 u_n}{dt^2} = \chi(|\varphi_{n+1}|^2 - |\varphi_{n-1}|^2) + \kappa(u_{n+1} + u_{n-1} - 2u_n) \quad (7)$$

The numerical simulation of these equations (and of extensions of these equations to the three interacting chains that are present in an α -helix (Scott, 1992)) confirmed Davydov's analytical studies in the continuum limit by showing that solitons can form and travel along the chains. It was also found that in the discrete chains there is a threshold in the nonlinearity parameter χ above which localized excitations can form. This threshold tends to zero as the length of the system increases.

Thermal Stability of Localized States

While the zero temperature results summarized above allow for the existence of soliton states in proteins, an important question is whether these states are stable at biological temperatures and, if not, how long they last. Coupling to a thermal bath was modeled by extending the equations of motion into Langevin equations, that is, adding stochastic forces $F(n)$ and damping terms $-\Gamma du_n/dt$ to the right-hand side of Equation (7), so that these terms obey the fluctuation-dissipation relations (Lomdahl & Kerr,

Figure 1. Dynamics of an amide-I excitation at biological temperatures.

1985): $\langle F_n(t) F_m(t') \rangle \geq 2M\Gamma k_B T \delta_{nm} \delta(t - t')$, k_B being the Boltzmann constant and T the temperature. The result is that soliton solutions disperse in a few picoseconds at biological temperatures. On the other hand, exact quantum Monte Carlo (QMC) simulations (Wang et al., 1989) showed that the distortion induced by the excitation increased with temperature. This conflict was resolved by showing that the coupling of a classical bath to a mixed quantum-classical system leads to a classical behavior of the quantum part (Cruzeiro-Hansson & Takeno, 1997). While the states of a classical excitation at finite temperature are predominantly delocalized, the states of a quantum excitation are predominantly localized. A set of dynamic equations, that leads to the same equilibrium averages as the QMC, leads to the following dynamics (Cruzeiro-Hansson & Takeno, 1997): instead of coherent propagation along the chain, as is expected from solitons, localized amide-I excitations jump stochastically from site to site, changing their shape and their velocity as they travel. It has been suggested that this stochastic propagation is a very robust way of transferring energy in proteins because it can survive mutations more than coherent propagation. Thus these simulations indicate that the Davydov model is indeed a possible mechanism for energy transfer in proteins (Cruzeiro-Hansson & Takeno, 1997).

Experimental Evidence

The first evidence for a Davydov-like state was obtained in a crystal of acetanilide (ACN), which includes hydrogen-bonded chains identical to those found in proteins. Careri and co-workers found an anomalous line, red-shifted by 15 cm^{-1} with respect to the amide-I vibration in that crystal (Scott, 1992). A series of studies established that this spectral line could not be attributed to a Fermi resonance, a Davydov splitting, or a phase transition. Its interpretation in terms of an interaction of an amide excitation with optical phonons provided good fits of the variation of its intensity with temperature as well as of its overtone frequencies. Careri and Wyman (see Scott, 1992) integrated the Davydov model in the so-called "turning wheel" model of enzyme action in which it is assumed that the binding

of ligands leads to the formation of solitons that are used to promote the enzymatic cycle.

An early objection to the role of vibrational excited states in proteins was their short lifetime, which was supposed to be in the subpicosecond range. Recently, Austin and co-workers have measured the lifetime of amide-I vibrations in myoglobin and found it to be 15 ps (Xie et al., 2000). Hamm and co-workers have also recently applied nonlinear spectroscopy to the study of ACN, not only to the amide-I band (Edler & Hamm, 2002) but also to the NH vibrations (Edler et al., 2002) that have approximately twice the energy of amide-I and a binding energy 20 times larger. In a pump-probe femtosecond spectroscopy experiment, they found that the ground state recovery for NH at room temperature is 20 ps and for amide-I at 90 K, it is 35 ps, and that the lifetime of NH stretch in the crystal is 20 times greater than in isolated ACN. Computer simulations show that vibrational excitations can travel tens of nanometers within the lifetime of these excitations (Cruzeiro-Hansson & Takeno, 1997). Edler & Hamm (2002) also find that while the low-temperature amide-I excitations are self-trapped, the higher temperature ones are Anderson-localized, in agreement with the predictions of the computer simulations (Cruzeiro-Hansson & Takeno, 1997).

Future Work

The theoretical work on the Davydov model shows that localized vibrational excited states can form in proteins and that they can be used to transfer energy from the active site to other regions of the proteins where this energy is used for work. The experimental evidence available corroborates this possibility. Further experiments should test the role of excited vibrational states in protein function in a more direct way. A theoretical challenge is to integrate the Davydov model in the full protein cycle and find out how vibrational energy transfer may eventually lead to a conformational change (Cruzeiro-Hansson & Silva, 2001), the well-known way in which proteins fold or transform into their permanent three-dimensional shapes.

DELAY COORDINATES

See **Embedding methods**

DELAY-DIFFERENTIAL EQUATIONS

A delay-differential equation (DDE) comprises an unknown function and certain of its derivatives, evaluated at arguments that differ by fixed numerical values. For example, $\dot{x}(t) = F(t, x(t), x(t-r))$ is a retarded DDE for $r > 0$.

DDEs can be characterized by the number of variables, the differential order, the order of the highest derivative appearing, and the difference order (one less than the number of different arguments appearing). DDEs (also called functional differential equations or difference-differential equations) generalize the concept of differential equations by allowing the state of the system to depend on states different from the present one, via, for example, a feedback mechanism.

DDEs appear in many fields, from economics to biology and from chemistry to mathematics, as the following examples suggest.

Bacterial Infection

In a book on the study of malaria published in 1911 (Ross, 1911), Ross considered a differential equation model of malarial epidemics based on the interaction of two populations, that of infected humans, described by $h(t)$, and that of infected mosquitoes, by $m(t)$. The relevant nonlinear DDEs are

$$\begin{aligned}\dot{h}(t) &= m(t-u) \frac{p-h(t-u)}{p} - (M+r)h(t), \\ \dot{m}(t) &= h(t-v) \frac{q-m(t-v)}{p} - (N+s)m(t), \quad (1)\end{aligned}$$

with p and q being the total populations, M and N the death rates, and r and s the recovery rates for human and mosquito populations, respectively. The delay from the time of a bite to the time at which the human or the mosquito is infective is $u = 0.5$ months for humans and $v = 0.6$ months for mosquitoes.

Enzyme Catalysis

Roussel (1996) presents a model of enzyme catalysis, proposed by Adrian Brown in 1902, in which the enzyme-substrate complex has a fixed lifetime τ before giving rise to its reaction products

The DDEs generated by this model are

$$\begin{aligned} \frac{dS(t)}{dt} &= -kE(t)S(t), \\ \frac{dE(t)}{dt} &= -kE(t)S(t) + kE(t - \tau)S(t - \tau), \\ \frac{dP(t)}{dt} &= kE(t - \tau)S(t - \tau), \end{aligned} \quad (3)$$

where k is the rate constant and by $E(t)$, $P(t)$, and $S(t)$, we mean the enzyme, product, and substratum concentrations.

Economic Dynamics

Delays can emerge in the dynamics of economic processes in two ways. First, there is a lag between the time economic decisions are taken and the time the decisions bear fruit. Also, the expected future values of a variable are functions of its current and past values. Let us consider a world in which infinitely many houses are inhabited, and let us consider the problem of finding the best time for constructing a new house (Asea & Zak, 1999).

The individuals' preferences are represented by a continuous, strictly increasing, and concave utility function $U(c(t))$. Subjective discount rates are characterized by $\rho > 0$. In this model, it takes $r > 0$ periods to obtain new capital. The solution of this planning problem is given by

$$\max_{\{c(t)\}} \int_0^{\infty} U(c(t))e^{-\rho t} dt, \quad (4)$$

subject to the DDE

$$\frac{dk(t)}{dt} = f(k(t - r)) - \delta k(t - r) - c(t), \quad (5)$$

with initial condition $k(t) = \phi(t)$, for all $t \in [-r, 0]$. $f(\cdot)$ is the production function; $c(t)$, the rate at which capital depreciates, such that $0 < c(t) \leq f(k(t - r))$, $\delta \in [0, 1]$; and $k(t)$, the productive capital stock at time t .

Mathematics

If one considers the symmetry reduction of a nonlinear differential-difference equation with respect to a combination of continuous and discrete symmetries, then the initial equation reduces to a DDE. As an

example, consider the Toda lattice (Levi & Winternitz, 1993)

$$\ddot{u}_n(t) = e^{u_{n-1}(t) - u_n(t)} - e^{u_n(t) - u_{n+1}(t)}, \quad (6)$$

and assume a reduction with respect to $\partial_n + a\partial_t$, where a is an arbitrary real parameter. Equation (6) then reduces to

$$\frac{d^2 u(\eta)}{d\eta^2} = e^{u(\eta+a) - u(\eta)} - e^{u(\eta) - u(\eta-a)}, \quad (7)$$

where $\eta = t - an$.

The equations considered in these examples are all instances of a general DDE, which, in the simple case of a linear first-order equation for just one field, can be written as

$$\begin{aligned} a_0 \frac{du(t)}{dt} + a_1 \frac{du(t - \sigma)}{dt} + b_0 u(t) + b_1 u(t - \sigma) \\ = f(t). \end{aligned} \quad (8)$$

An equation of the form (8) is said to be a DDE of *retarded* type if $a_0 \neq 0$ and $a_1 = 0$; it is said to be of *neutral* type if $a_0 \neq 0$ and $a_1 \neq 0$; and of *advanced* type if $a_0 = 0$ and $a_1 \neq 0$.

In applications, an equation of *retarded* type may represent the behavior of a system in which the rate of change of $u(t)$ depends on its past and present values. A *neutral* equation represents a system in which the present rate of change depends on past rates of changes as well as its present and past values. An *advanced* type equation may represent a system in which its rate of change depends on its present and future values.

If $a_0 = a_1 = 0$, Equation (8) is a pure difference equation, while if $a_0 = b_0 = 0$ or $a_1 = b_1 = 0$, it is a pure differential equation. In either case, $f(t)$ is a forcing function.

Let us compare the solution techniques for DDEs with those of ordinary differential equations (ODEs) and note some of their peculiar features. For simplicity we limit ourselves to retarded DDEs. For more details, see Bellman & Cooke (1963), Hale (1977), Hale & Verduyn Lunel (1993), Driver (1977), Bainov & Mishev (1991), Kuang (1993), and Gyori & Lada (1991).

Because retarded DDEs depend on previous history, the initial condition at one point is not sufficient to obtain the present time behavior. What one needs depends on the discrete order of the equation. If the equation is a DDE of first order, then the initial solution on a whole delay interval is needed.

For constant coefficient DDEs, an algebraic method of solution is provided by the "method of steps," which also provides a constructive proof of the existence of the solution. To illustrate this method, consider a DDE generalization of the logistic equation

$$\frac{dx(t)}{dt} = -cx(t - 1)[1 + x(t)], \quad t > 0, \quad (9)$$

with the initial condition $x(t) = \phi(t)$ for $t \in [-1, 0]$. To solve Equation (9), we divide the interval $[0, \infty)$ into steps of the size of the delay and solve recursively in each interval. We use the solution obtained in one interval to solve Equation (9) in the next one. For example, the solution in the interval $[0, 1]$ is given by

$$x(t) = [\phi(0) + 1]e^{-c \int_0^t \phi(s-1)ds} - 1,$$

which is obtained as a solution of the ODE

$$\frac{dx(t)}{dt} = -c\phi(t-1)[1+x(t)]. \quad (10)$$

For linear DDEs we can construct, as in the case of linear ODEs, the characteristic equation, by looking at exponential solutions. In this case, however, the characteristic equation is given by a nonlinear algebraic equation. For example in the case of Equation (8), with $a_1 = 0$, we have

$$h(\lambda) = a_0\lambda + b_0 + b_1e^{-\lambda\sigma} = 0. \quad (11)$$

Once the characteristic equation is solved, a particular solution of the DDE is obtained by applying the Laplace transform (Bellman & Cooke, 1963).

As we have seen, the nature of the method of solution of a DDE is similar to that of an ODE. Nevertheless, DDEs exhibit more complicated behaviors, even in the linear case. For example, scalar linear first-order homogeneous DDEs with real coefficients can have nontrivial oscillating solutions unlike ODEs (Kalecki, 1935). Moreover, solutions to DDEs may be discontinuous and, depending on the initial conditions, a solution may also not exist (Winston & Yorke, 1969). As in the case of ODEs, series solutions can be used to approximate solutions to nonlinear DDEs (Bellman & Cooke, 1963); however, the solutions obtained are often complicated and obscure.

We can gain a better insight into the solution using qualitative theory and stability analysis to obtain properties of the dynamics of a nonlinear DDE by looking at its linearization.

The stability of a fixed point of a DDE is defined by examining the roots of the characteristic equation $h(\lambda)$. Thus, a fixed point of a DDE is stable if all roots of $h(\lambda)$ have negative real parts. As the characteristic equation (11) is transcendental, it has an infinity of roots, and it is not guaranteed that all roots will have real parts, strictly negative or positive. So fixed points of DDEs will often be saddle points. Moreover, stability may depend crucially on the initial data (Driver, 1977).

The stability of homogeneous scalar DDEs of the first order has been studied by Hayes (Bellman & Cooke, 1963). These results can be extended to nonlinear systems by linearizing the DDE around a stable solution and then using a generalization of the Poincaré-Lyapunov theorem. In such a way, one can

show that DDEs often admit periodic solutions after a sequence of Hopf bifurcations. Chaotic orbits may also exist, with the structure of the orbits depending critically on the smoothness of the feedback mechanism.

DENJOY THEORY

The theory developed by Arnaud Denjoy (1884–1974) showed that any sufficiently smooth orientation-preserving diffeomorphism T of the unit circle S^1 with an irrational rotation number ρ is topologically equivalent to a linear rotation by the angle $2\pi\rho$ (Denjoy, 1932). Informally, diffeomorphism is a smooth invertible map such that its inverse is also smooth.

Circle diffeomorphisms arise naturally in many physical problems. For instance, in the case of Hamiltonian systems with two degrees of freedom, such diffeomorphisms appear as Poincaré first return maps for the two-dimensional invariant tori. When the rotation number is irrational, circle diffeomorphisms represent an important model for quasi-periodic dynamics (*See Quasiperiodicity*). The Denjoy theory

implies the following important fact: if two smooth circle maps have the same irrational rotation number then the topological structure of their trajectories is exactly the same.

The topological equivalence means that circle diffeomorphisms are conjugated to a linear rotation with the help of a homeomorphic change of variables. Namely, there exists a homeomorphism, ϕ , which is an invertible map that is continuous together with its inverse, such that $T \circ \phi = \phi \circ T_\rho$, where T_ρ is the linear rotation by the angle $2\pi\rho$ and $\circ$ stands for a composition of two maps. Denjoy's theorem holds if T is absolutely continuous and $\log T'(x)$ has bounded total variation: $V = \text{Var}_{S^1} \log T'(x) < \infty$. The last condition is satisfied if T is C^2 -smooth and $T'(x) > 0$. The conjugacy ϕ is defined uniquely up to an arbitrary rotation T_θ . In fact, a mapping ϕ of the unit circle S^1 that satisfies condition $T \circ \phi = \phi \circ T_\rho$ can be constructed for any quasi-periodic homeomorphisms T . This means that any homeomorphism T with irrational rotation number ρ is semiconjugate to T_ρ . However, if T is not regular enough, ϕ may not be a homeomorphism. To construct ϕ it is enough to take two arbitrary points x_0 and y_0 and define their forward trajectories by T and T_ρ , respectively: $x_i = T^i x_0$, $y_i = T_\rho^i y_0$, $i \geq 1$. Now one can define ϕ on $\{y_i\}$ by letting $\phi(y_i) = x_i$, $i \geq 0$ and extending ϕ by continuity to the whole unit circle. This can be done since any trajectory of a linear rotation by an irrational angle is everywhere dense. It is easy to see that a conjugacy ϕ is a homeomorphism if and only if T is transitive; that is, all its trajectories are dense on S^1 .

When the total variation V is bounded, the transitivity of T follows from the Denjoy inequality:

$$\exp(-V) \leq \prod_{i=0}^{q_n-1} T'(x_i) \leq \exp(V),$$

where q_n are the denominators of the convergents $p_n/q_n = [k_1, k_2, \dots, k_n]$, and $\rho = [k_1, k_2, \dots, k_n, \dots]$ is the continued fraction expansion for ρ . The condition $T \in C^2(S^1)$ that implies topological equivalence is almost sharp. Indeed, Denjoy constructed counterexamples where $T \in C^1(S^1)$ and the derivative $T'(x)$ is a Hölder continuous function with an arbitrary Hölder exponent $0 < \alpha < 1$. In these examples T is not transient and, hence, is not conjugate to T_ρ .

An important extension of the Denjoy theory is connected with the problem of smoothness of the conjugacy ϕ . It is natural to ask when the homeomorphism ϕ is at least C^1 -smooth, which implies not only topological but also asymptotic metrical equivalence between T and T_ρ . In this case, the unique probability invariant measure for T is absolutely continuous with respect to the Lebesgue measure. The first progress in this direction was made by Arnol'd (1961), who proved that for analytic diffeomorphisms,

T that are close enough to the linear rotation T_ρ , a conjugacy ϕ is analytic provided the rotation number ρ is Diophantine, that is, $\|\rho - p/q\| \geq 1/q^{2+\delta}$ for some $\delta > 0$ and all integers p, q . Diophantine numbers form a set of positive Lebesgue measure and, hence, are typical in the Lebesgue sense. Arnol'd has also constructed counterexamples in the case of nontypical rotation numbers, which show that the smooth theory cannot be constructed for all irrational rotation numbers. In these counterexamples, ϕ is not differentiable, and the invariant measure for T is essentially singular with respect to Lebesgue measure. Arnol'd's results are of the KAM-type (Kolmogorov–Arnol'd–Moser) and, hence, have a local character. However, as it was conjectured by Arnol'd, in the one-dimensional case the local condition of T being close to T_ρ should not be necessary, and the global result should hold for all T smooth enough. Such a global result has been proven by Herman (1979) in the case when ρ satisfies certain Diophantine condition and $T \in C^3(S^1)$. Later Herman's results were extended to a wider class of rotation numbers (Yoccoz, 1984) and to diffeomorphisms $T \in C^{2+\varepsilon}(S^1)$ (Khanin & Sinai, 1987; Sinai & Khanin, 1989; Katznelson & Ornstein, 1989).

Finally, we mention another extension of the Denjoy theory to the case of diffeomorphisms with singularities. Such mappings appear, for example, in the case of critical invariant tori in Hamiltonian systems with two degrees of freedom. The extension of the Denjoy theory to this case is a subject of the so-called rigidity theory. The main aim is to find conditions which imply that two topologically equivalent homeomorphisms that have the same local structure of their singular points are, in fact, C^1 -smoothly conjugate to each other. Significant progress in this direction has been made in the last 5 years in the case of mappings with one singular point (de Faria & de Melo, 1999, 2000; Yampolsky, 2001; Khanin & Khmelev, 2003). Note that the presence of singularities makes rigidity stronger than in the case of smooth diffeomorphisms. The arithmetical properties of the rotation numbers are less important, and one should expect C^1 -rigidity for all irrational rotation numbers.

DERIVATIVE NLS EQUATION

See **Nonlinear Schrödinger equations**

DERRICK–HOBART THEOREM

The Derrick–Hobart scaling argument concerns certain solutions of nonlinear partial differential equations that arise as models for elementary particles; thus they are mostly of the relativistic variety. To appreciate the context in which the argument arose and the way it is used, some introductory remarks on relativistic quantum field theory are in order.

There are only a few interacting relativistic quantum field theories that have been solved explicitly, in the sense that physically relevant quantities (particle spectrum, scattering, form factors, and so on) are known in closed form. For all of these models the dimension of space-time equals two. To gain more insight into higher-dimensional models, it has become standard practice to study the field theory first as a classical field theory. The underlying idea is that (via the Feynman path integral) one can use classical findings to obtain nonperturbative information on the quantum version. In particular, the presence of nonconstant, smooth, stable, time-independent, finite-energy, classical solutions is believed to signal the presence of an associated stable quantum particle.

The notion of “stability” refers to small fluctuations around such a classical finite-energy solution. To first order, such variations do not change the energy, as

expressed by the Euler–Lagrange equation. To second order, however, the energy may become smaller, in which case the corresponding quantum particle is considered to be unstable. (Think of a ball resting on top of a hill. A little push makes it roll down.)

In order to study the existence of nonconstant finite-energy solutions (either stable or unstable), an argument due independently to Derrick (1964) and (in a somewhat different form) to Hobart (1963) is often useful. These authors were concerned with three-dimensional space (four-dimensional space-time), but the argument can be extended without difficulty to an arbitrary space dimension N . Briefly, the argument is as follows.

Assume $\phi(x, t)$, $x \in R^N$, $t \in R$, is a scalar field on $(N + 1)$ -dimensional space-time, whose dynamics is given by the Lagrangian

$$\mathcal{L} = \frac{1}{2}(\partial_t \phi^2 - \nabla \phi \cdot \nabla \phi) - V(\phi), \quad (1)$$

with $V(y)$ being a potential function. Now let $\phi(x)$ be a (smooth) time-independent nonconstant solution to the Euler–Lagrange equation, with finite energy

$$E = E_{\text{kin}} + E_{\text{pot}}, \quad E_{\text{kin}} = \frac{1}{2} \int_{R^N} \nabla \phi \cdot \nabla \phi dx, \\ E_{\text{pot}} = \int_{R^N} V(\phi) dx. \quad (2)$$

Starting from the above data, Derrick's key idea is to consider the family of scaled functions

$$\phi_\lambda(x) = \phi(\lambda x). \quad (3)$$

Clearly, the energy associated with ϕ_λ is given by

$$E_\lambda = \lambda^{(2-N)} E_{\text{kin}} + \lambda^{-N} E_{\text{pot}}, \quad (4)$$

so that

$$(dE_\lambda/d\lambda)_{\lambda=1} = (2 - N)E_{\text{kin}} - NE_{\text{pot}}, \quad (5)$$

$$(d^2 E_\lambda/d\lambda^2)_{\lambda=1} = (2 - N)(1 - N)E_{\text{kin}} \\ + N(N + 1)E_{\text{pot}}. \quad (6)$$

Since ϕ_λ makes the energy stationary for $\lambda = 1$, we have

$$(dE_\lambda/d\lambda)_{\lambda=1} = 0. \quad (7)$$

Hence (5) yields

$$E_{\text{pot}} = \frac{2 - N}{N} E_{\text{kin}}, \quad (8)$$

which entails

$$(d^2 E_\lambda/d\lambda^2)_{\lambda=1} = 2(2 - N)E_{\text{kin}}. \quad (9)$$

Let us now draw the relevant conclusions from this simple calculation. Since $\phi(x)$ is nonconstant, its

kinetic energy E_{kin} is positive. For $N > 2$, then, (9) says that the finite-energy solution cannot be stable. This is the first consequence, an instability result for $N > 2$. It does not involve restrictions on the potential $V(y)$.

Assuming from now on that $V(y) \geq 0$, far stronger conclusions can be drawn. Indeed, since ϕ_λ is a solution for $\lambda = 1$, $\phi_1 = \phi$ makes the energy stationary. But since ϕ is nonconstant, we have $E_{\text{kin}} > 0$, and since $V \geq 0$, we also have $E_{\text{pot}} \geq 0$. Therefore, the right-hand side of (5) is negative for $N > 2$, a contradiction. A second consequence, therefore, is the absence of finite-energy nonconstant solutions for $V \geq 0$ and $N > 2$.

Retaining the assumption $V \geq 0$, one can draw a conclusion for $N = 2$, too. Indeed, it then follows that $E_{\text{pot}} = 0$, so that ϕ must satisfy $V(\phi) = 0$; moreover, the second variation (6) vanishes.

For $N = 1$ the variation formulas (5), (6) have no useful consequences. Indeed, in two-dimensional space-time there do exist stable time-independent finite-energy solutions, as exemplified by the one-soliton and one-antisoliton solutions of the sine-Gordon theory.

In applications of Derrick's argument, one usually encounters positive potentials and invokes the latter consequences sketched above. Thus, it is used to the effect that for $N \geq 2$, time-independent finite-energy solutions must be constant (the so-called vacuum solutions). Some caveats should be heeded, however.

First, it is important to keep track of the above steps in models that are not of the above form, since the reasoning may need to be suitably modified. Second, even when this can be done at face value, it should be observed that the above argument, although convincing at first sight, is not a rigorous proof. Indeed, the scaling variation that is involved has a global character, whereas the Euler-Lagrange equation is derived by considering local variations. More in detail, one needs to control boundary terms that can *a priori* spoil the above derivation. (This was already realized in Hobart (1963).)

We exemplify these related issues with two models described by Lagrangians that are different from the above, namely a (special) Yang-Mills/Higgs model in physical space ($N = 3$) and a class of nonlinear σ -models for $N \geq 2$. In the first setting, explicit static finite-energy solutions were obtained in Prasad & Sommerfield (1975) and Bogomolnyi (1976). (These are nowadays called BPS monopoles.) The energy of these solutions is manifestly not scale-invariant, contradicting (7) for the case at hand. Inspection of the solution shows that this is due to poor decay at spatial infinity; it entails that the pertinent boundary term cannot be ignored.

Turning to $O(3)$ σ -models, one can once more study the issue of finite-energy solutions by adapting Derrick's scaling argument. For $N = 2$ (now viewed as Euclidean space-time) this yields no conclusion, since the energy is scale-invariant. In this case, the so-called

instanton and anti-instanton solutions do exist, and they are stable for topological reasons.

For $N > 2$, the scaling argument leads to the absence of finite-energy solutions. In this particular setting, the heuristic reasoning can be corroborated. More specifically, the boundary term can be rigorously controlled. The pertinent result (Garber et al. (1979), Theorem 5.1) has later been used by differential geometers to prove the nonexistence of harmonic maps, which are closely related to the above type of solution.

DETAILED BALANCE

This entry provides a qualitative discussion of equilibrium, a more quantitative discourse of principles such as detailed balance (which are needed in the description of equilibrium phenomenon), and a brief presentation of the Einstein relation between mobility and diffusion, which can be related to the above topics.

The Problem of Time

One often says that a system has reached an equilibrium state if its physical variables are constant in time. Because of fluctuations that cannot be removed, however, it is better to regard the system as in equilibrium when there are no systematic trends in the time averages of its physical parameters. Here, averages are considered over all the microscopic constituents of the system, whether they are elementary particles, atoms, molecules, or larger objects. Equilibrium can be established among these constituents.

Thus, a system that is in equilibrium cannot reveal the time variable among its broad characteristics. In other words, there is no way of telling which way time is running if one's observations are confined to an equilibrium system. Formulated as a philosophical puzzle about the nature of time, this subject has spawned a library of books and papers, with little

agreement among the authors (see Landsberg, 1982; Smith, 1993; Price, 1996; Davies, 1995).

Some Relevant Principles of Statistical Mechanics

Here and below, we shall deal with a number of important principles that may or may not hold in any given case and are related to each other. To make these matters quantitative, denote by P_i the probability of finding a system of interest in any one of the i th group of states, G_i in number. The probability per unit time that a transition occurs from a state of group i to a state of group j is denoted by A_{ij} . The transition rate $i \rightarrow j$ can be written as

$$R_{ij} = P_i A_{ij} G_j. \quad (1)$$

If there are W available groups of states, the time rate of change of P_i is

$$\dot{P}_i = \sum_{l=1}^W (R_{li} - R_{il}) \quad (i = 1, 2 \dots W). \quad (2)$$

To be tractable the A_{ij} have to be independent of time. The first sum gives the transitions into states i and the second sum gives the transitions out of the states i . To simplify the picture one can replace a typical group of states i by a single state, i.e., one can put $G_i = 1$.

Now some additional general principles can be defined. The existence of the A_{ij} can be deduced from quantum mechanical perturbation theory, but it is then valid only for a restricted time interval. One often finds the symmetry relation

$$A_{ij} = A_{ji} \quad (\text{all } i, j) \quad (3)$$

as a result of the Hermitian character of the perturbation operator. In statistical mechanics, one also uses the principle of Equation (3). It can then be independent of perturbation theory and is regarded instead as resulting from adequate statistical assumptions. It is then called the *principle of microscopic reversibility*.

Next we have the principle of detailed balance which asserts that at a certain time t the forward and reverse transition rates between two groups of states are equal at a certain time; thus,

$$R_{ij} = R_{ji} \quad (\text{all } i, j). \quad (4)$$

If Equation (4) holds, one sees that $\dot{P}_i$ vanishes for all i . In fact, we can define a steady state by

$$\dot{P}_i = 0 \quad (\text{all } i). \quad (5)$$

Such a state need not be an equilibrium state since the system may, for example, be continuously raised to a high energy state by some external influence and then drop back continuously, for example, by the emission of radiation. Thus, one sees that Equation (4) implies Equation (5), but not conversely. For more details, see Lifschitz & Pitaewski (1981) and Landsberg (1991).

A Simple Example from the Solid State

One can use detailed balance arguments to infer the form of an unknown emission rate from a known absorption rate, as will now be shown by an example (Landsberg, 1991, p. 391). The idea is to obtain an expression for the equilibrium absorption rate per unit volume of photons of frequency ν_0 in a semiconductor of refractive index μ and, hence, to infer spontaneous emission rates per unit volume.

The probability of a single photon of vacuum wavelength λ_0 being absorbed per unit time per unit volume is

$$P(\lambda_0) = c\alpha(\lambda_0)/V\mu(\lambda_0). \quad (6)$$

The dimensions ($LT^{-1} \cdot L^{-1} \cdot L^{-3}$) are easily verified to be correct. To find the volume rate of excitation in the solid by photons in the vacuum wavelength range $d\lambda_0$, $P(\lambda_0)$ has to be multiplied by the number of relevant photon modes ($8\pi\mu^3\lambda_0^{-4}Vd\lambda_0$), and also by their equilibrium occupation probability at temperature T :

$$1/[\exp(ch/\lambda_0 kT) - 1]. \quad (7)$$

But not all photons of wavelength λ_0 will, when absorbed, produce one electron-hole pair. We denote by $\alpha'(\lambda_0)/\alpha(\lambda_0) (\leq 1)$ the probability of this happening per absorbed photon. Hence, the equilibrium absorption rate (per unit volume) of photons in the wavelength range $d\lambda_0$ with production of an electron-hole pair is

$$\alpha'/\alpha \frac{8\pi\mu^2 c \lambda^{-4}}{\exp(ch/\lambda_0 kT) - 1} d\lambda_0$$

or

$$\frac{8\pi\alpha'}{h^3} \frac{\mu}{c^2} (kT)^3 \frac{x^2 dx}{\exp x - 1}. \quad (8)$$

Here $x = h\nu_0/kT$, and the second of these expressions is like the first, except that it is in terms of frequencies. According to detailed balance, the new inference is that these expressions give the rate per unit volume of spontaneous radiated recombination of electron-hole pairs with the emission of photons in the range $d\lambda_0$ or $d\nu_0$. Note that we have passed from absorption to emission data. This widely used result was first given by W. van Roosbroeck and W. Shockley in 1954. For other examples of the use of the principle of detailed balance in solid state physics, see Landsberg (1991).

The Einstein Relation

The Einstein Relation is basic to solid states physics and rests on the assumption that in a steady state the flux of charged particles due to an electric field must be balanced by diffusion of these particles induced by their density gradients. These two effects are due to well-known and simple forces. The first is a particle flux due

to diffusion (with diffusion coefficient D , say). It can be written $-Ddn/dx$ for one-dimensional motion, where n is the density of particles and dn/dx the gradient ("grad n " in three dimensions). The minus sign shows that the force acts to the left if the concentration n increases to the right. The second force on the charged particles is due to a built-in or externally applied electric field E , which is a vector in three dimensions. Here we deal merely with the one-dimensional problem, and note that E can be replaced by $-dV/dx$, where V is the electrostatic potential at the point considered. The flux of particles can be written as $nvE = -n\mu dV/dx$, where v is the so-called mobility of the particles.

In order to obtain the Einstein relation in its simplest form, one has to equate the two forces

$$-n\mu \frac{dV}{dx} = D \frac{dn}{dx}, \quad (9)$$

which implies that

$$\frac{d(\ln n)}{dx} = -\frac{\mu}{D} \frac{dV}{dx} \quad (10)$$

giving the simple result

$$n = n_0 \exp(-\mu V/D). \quad (11)$$

As we also know that the stationary state in an electric field at a temperature T is governed by the Boltzmann distribution

$$n = n_0 \exp(-eV/kT), \quad (12)$$

where n_0 is a constant and k is Boltzmann's constant. Comparison yields the Einstein relation

$$\mu = eD/kT. \quad (13)$$

This result connects the mobility of charged particles in a field with their diffusion coefficient. At first sight this seems unexpected because one side of the equation deals with the mechanical characteristic of diffusion.

The extension to three dimensions is not the only generalization that can be made. For example, a similar Einstein relation holds for thermal current density, and generalizations have also been made for large departures from equilibrium (Landsberg, 1991). A further variety of special cases arises for different assumptions about the shape of the semiconductor bands that can occur; for example, they can be degenerate or nondegenerate, parabolic or nonparabolic, etc., and the results can be given in a table of formulae. (Einstein's paper was published in *Annalen der Physik und Chemie* in 1905, the first of three important papers published by him in that year.)

The principle of detailed balance emerged somewhat hesitantly in the 1920s, based on Einstein's 1917

paper on transition possibilities. It was named by Fowler and Milne following other authors and other names. A brief historical survey is given by ter Haar (1955).

DETERMINISM

Determinism is a philosophical and scientific notion, and discussions about it are as old as philosophy and science themselves. Richard Taylor writes "Determinism is the general philosophical thesis which states that for everything that ever happens there are conditions such that, given them, nothing else could happen" (Taylor, 1996). This seems to be the most general formulation of determinism. In philosophy, he continues, "There are five theories of determinism to be considered, which can for convenience be called ethical determinism, logical determinism, theological determinism, physical determinism, and psychological determinism." Here we shall confine ourselves only to physical determinism in the natural sciences, except in the concluding section.

In physics, the deterministic view developed along with the experimental approach to research, in the sense that phenomena are reproducible under the same unchanged external conditions, implying that the same cause leads to the same consequences under the same conditions. The quantitative description of physical reality began with Galileo Galilei; although some early developments are due to Pythagoras. However, Isaac Newton was the first to lay down the complete basis of classical mechanics, which at the time was considered to be the origin of all physical phenomena. His laws of mechanics plus

the law of gravitation enabled him to reproduce and mathematically derive the motion of the planets, observations of which were empirically well known by the beginning of the 16th century and formulated in Johannes Kepler's laws of celestial mechanics. With the rise and development of classical mechanics the view of determinism developed, with the opinion that all natural laws can be described by dynamical equations, either ordinary differential equations (as, for example, in celestial mechanics) or partial differential equations (as, for example, in the dynamics of fluids). In each case precise knowledge of the initial conditions (all positions and all velocities) completely determines the entire future and entire past of the system. When pushed to its extremum, this view implies complete deterministic evolution of the entire universe, including all its smallest and largest details. The French mathematician Pierre Simon de Laplace, about one century after Newton, wrote (in an often quoted passage):

We ought then to regard the present state of the universe as the effect of its antecedent state and the cause of the state that is to follow. An intelligence knowing, in any instant of time, all forces acting in nature, as well as the momentary positions of all things of which the universe consists, would be able to comprehend the motions of the largest bodies in the world and those of the smallest atoms in one single formula, provided it were sufficiently powerful to subject all data to analysis: to it, nothing would be uncertain, both future and past would be present before its eyes. (Laplace, 1814)

We can comment on Laplace's statement from our modern perspective. First, to store and process data of *infinite precision* about the state of the entire universe is problematic, as it would require a computer that would be of comparable size and complexity to the entire universe. Thus, its presence has to be taken into account, since—obeying the same mechanical laws as the rest of the universe—it would itself disturb the universe. Therefore, we can conclude that Laplace's "intelligence" (sometimes known as Laplace's daemon) cannot exist, and consequently his idea is fiction. Second, infinite precision of all the initial conditions (positions and momenta) can never be achieved in practice. And when the precision is finite, the existence of chaos (positive Lyapunov exponents) implies sensitive dependence on initial conditions and exponential divergence of nearby trajectories. In other words, there is a finite time horizon exists in general chaotic mechanic systems, beyond which nothing at all can be predicted (Lyapunov time). Therefore, the modern notion of omnipresent chaotic behavior makes Laplace's idea impossible to implement, even in principle. Third, the universe is not described by classical mechanics, but by quantum mechanics, classical mechanics being just a useful or even excellent approximation in observing and describing the motions of sufficiently large bod-

ies. Quantum mechanics tells us, through Heisenberg's principle of uncertainty, that momenta and positions cannot be measured simultaneously with infinite precision, but we have instead the inequality $\Delta x \Delta p_x \geq \hbar/2$, where Δx and Δp_x are the uncertainties of position x and the conjugated momentum p_x . So, Laplace's initial conditions can never be known to arbitrary precision, even in principle.

Quantum mechanics is the correct description of physical reality, with the Schrödinger equation as the starting tool, for nonrelativistic systems. The quantum theory has been further developed by Paul Dirac for relativistic quantum systems and by the quantum field theory up to the unifying field theories, which capture three fundamental interactions (electromagnetic, weak, and strong interactions), but not yet gravity. The Schrödinger equation is a deterministic equation of motion of the wave function ψ , which contains the complete description of the quantum state of a given system. Importantly, ψ itself is a statistical quantity and thus not deterministic: it gives merely probabilities for the given system to be found (by measurement) in a given state.

This is the so-called Copenhagen interpretation of quantum mechanics, initiated by Max Born in 1926 and further developed by Niels Bohr and his colleagues, according to whom there is no determinism in physical reality. This view was strongly opposed by Albert Einstein and colleagues, who accepted the quantum theory as correct but thought that it was an incomplete theory, to be supplemented (through future research) by a more general deterministic theory, uncovering further "hidden variables," which seem to be ignored in present-day quantum mechanics. Many attempts have been made to find such a classical theory of fields to deduce the quantum theory but without success. There are also certain predictions such as Bell's inequalities that are the testing ground of whether quantum theory can in principle be an extended classical deterministic field theory. So far the answer is no, at least for a large class of "local hidden variables theories," and today we do have experimental confirmations where Bell's inequalities are experimentally violated, meaning that the quantum theory and its prediction for the outcome of such experiments is correct. Therefore, the statistical interpretation of quantum mechanics of Bohr's Copenhagen school, together with the strongly counter-intuitive notion of nonlocality, is proven to be correct, and these non-deterministic properties of quantum mechanics are being used in technological applications (such as quantum information theory, quantum teleportation, and quantum computing).

It is, of course, a philosophical shock to learn that the world is not deterministic, but there seems to be no way out. One of the main causes is the process of quantum measurement, which as a process is *not* described by the Schrödinger equation and seems to

be the primary source of quantum indeterminism. Quantum measurement is the main source for the generally accepted statistical interpretation of quantum mechanics. Still, the potential of a classical nonlinear field theory (including its turbulent solutions) seems largely unexplored as a description of physical reality. Even classical nonlinear dynamics is not deterministic (even in principle) due to the existence of chaos. A nonlinear classical field theory is even richer, for example the complex turbulent solutions of the Navier–Stokes equations.

In a deterministic world, there would be no place for free will in the lives of human beings or other living creatures. Everything would be predetermined by the initial state before our life, even if we do not have information about that, which implies that we cannot be aware of our predestination. Since the world is not deterministic, there is room for free will and free choice. However, it might be that the world is deterministic, if we do not observe it, and is not deterministic as soon as we “touch” it. Therefore, determinism can never be proved (in analogy with Kurt Gödel’s famous incompleteness theorem). Thus, our free will may materialize as soon as we interact with the world, otherwise we would be completely predestined, but isolated from the rest of the world, which is of course not possible. The issue of classical and quantum measurement lies at the bottom of such discussions. It leads to the general conclusion that the world ultimately is not deterministic, but determinism might be a good approximation under certain conditions imposed on the measurement process.

DETERMINISTIC WALKS IN RANDOM ENVIRONMENTS

A “deterministic walk in a random environment” (DWRE) is the name given to a system generated by the motion of some object (such as, a particle, signal, wave, ant, read/write head of the Turing machine) on a graph. At each time step, the object hops from a vertex to one of its neighboring vertices. The choice of neighbor is completely determined by the type of deterministic scattering rule or scatterer, located at the vertex. A random environment is formed by the scatterers that are assumed to be initially randomly (usually independently) distributed among the vertices. DWREs (in their simplest form and under different names) were introduced in various branches of science (Gunn & Ortuño, 1985; Langton, 1986; Ruijgrok & Cohen, 1988) as paradigms, for example, for propagation of a signal in a random media, evolutionary dynamics, growth processes, and the computational environment.

In the early numerical studies, graphs were regular lattices and usually two types of scatterers were considered in each model. The most studied case was that of the regular quadratic lattice with left and right rotators, which rotate the particle to the left or to the right by an angle $\pi/2$, or left and right mirrors aligned along the two diagonals of the lattice. Two classes of such models have been extensively studied numerically (Cohen, 1992). The first class corresponds to the case when there is no feedback of the moving particle to the environment; that is, a particular type of scatterer is fixed at each site of the lattice forever. Another class is formed by models with flipping scatterers, when a scatterer at a site changes (deterministically) after every visit of a particle to this site.

In statistical physics, these models naturally appear as deterministic Lorentz lattice gases (but with a random distribution of scatterers). The scatterers are not spheres (disks) as in the classical Lorentz gas. Instead, say in the d -dimensional cubic lattice, there are $(2d)^{2d}$ different types of scatterers because each vertex in this case has $2d$ incoming and $2d$ outgoing edges. In theoretical computer science, these models are referred to as many-dimensional Turing machines because the changes of scatterer type at each vertex occur deterministically—according to some program written on an infinite tape divided into commands, for example, to change a given scatterer to some other type (Bunimovich & Khlabystova, 2002a).

Although a DWRE reminds one of random walks, these systems are essentially different. The major difference with random walks is that instead of carrying out a random experiment (like flipping a

coin), the particle chooses each step deterministically. Formally, DWREs are deterministic cellular automata, but their behavior reflects a mixture of deterministic dynamics and a random environment. Their dynamics is often counterintuitive (Cohen, 1992) because one's intuition is essentially based on exactly understood (completely solved) systems and models. There are many such models among purely deterministic and purely stochastic systems; however, there were basically no completely understood systems with a mixture of deterministic and stochastic features. Some subclasses of DWREs provide such exactly solvable models (Bunimovich, 2000).

Although closest to stochastic systems, DWREs have fixed environments. This seems counterintuitive, but the evolution of scattering types makes the entire dynamics more deterministic than in the case where an (initially random) distribution of scatterers is frozen.

In many cases, DWRE systems are equivalent to various models from percolation theory (Bunimovich & Troubetzkoy, 1992). Not only the structure of the graph (lattice) but also the types of scatterer in the model determine the corresponding percolation problem. For instance, the mirror's model in the square lattice is reduced to the percolation problem on the square lattice, while the rotator's model is reduced to the percolation problem on some nonplanar graph (Bunimovich & Troubetzkoy, 1992).

Perhaps the most widely known DWRE models are Langton's Ant (Langton, 1986) or the flipping rotators model on the square lattice (Ruijgrok & Cohen, 1988), which are solvable again with rather counterintuitive results (Bunimovich & Troubetzkoy, 1993). If all vertices are occupied with rotators, then all orbits (particle's paths) are unbounded. If, on the other hand, one allows vertices to be empty with positive probability (i.e., the third, straight-ahead scatterer is allowed), then the particle's path becomes bounded with probability one.

The results, both numerical and mathematical, continued to surprise until "Walks in Rigid Environments" (WRE) were introduced and analyzed (Bunimovich, 2000). WREs employ a new integer parameter r , $1 \leq r \leq \infty$, which is called the rigidity of the environment. The rigidity determines how many times the particle must collide with the given scatterer in order to change its type. In other words, the scatterer at a given vertex changes its type immediately after the r th visit of the particle to this site. Therefore, WREs interpolate between DWREs with fixed environments (where $r = \infty$) and DWREs with flipping environments (where $r = 1$).

WREs on a one-dimensional lattice $\mathbb{Z}$ are completely solved (Bunimovich, 2000; Bunimovich & Khlabytova, 2002b). In this case, there are only four types of scatterers. Two of them (forward scatterer and backscatterer) are symmetric with respect to the reflection of $\mathbb{Z}$, which

is the only nontrivial symmetry of the one-dimensional lattice. The other two scatterers, which always send the particle to the right (or to the left), do not respect this symmetry. Therefore, the WRE with the last two types of scatterers has the same behavior for all values of the rigidity r . This model demonstrates a diffusive type of behavior, in which the particle eventually visits all vertices and the mean square displacement of the particle is proportional to t . On the contrary, WREs with forward and back scatterers demonstrate totally different behavior depending on the parity of the rigidity r . For even rigidities, the particle eventually visits all vertices again but its motion is subdiffusive. The most interesting behavior occurs for odd values of the rigidity. In this case the particle—after a short initial period of seemingly irregular motion near the origin—starts to propagate in one direction with random velocity. This phenomenon of (eventual) propagation reminds one of "gliders" in Conway's Game of Life. However, in a WRE this propagation occurs for all initial configurations of environment, while in the Game of Life, gliders appear as only very special solutions. The phenomenon of eventual propagation in one direction is not restricted to one-dimensional WREs. For instance, the same behavior is demonstrated by the model with right and left rotators on the triangular lattice (Grosfils et al., 1999).

If the rigidity $r < \infty$, then one can also investigate the dynamics of the environment. Observe that if $r < \infty$, then it makes sense to consider not one but many moving particles as well. Indeed, even though the particles do not interact directly, they do effectively interact by changing environments with each other. The evolution of the environment in such models can be chaotic having a positive and even infinite metric entropy (Bunimovich & Troubetzkoy, 1993). This means, in particular, that the moving particle sees itself surrounded by almost any possible environment of scatterers at different moments of time.

An important difference between DWREs and random walks is that in the continuous limit DWREs become completely deterministic (Bunimovich & Khlabytova, 2002b), whereas biased random walks under proper scaling of probabilities become in the continuous limit stochastic diffusion processes.

DEVELOPMENT OF SINGULARITIES

For some nonlinear PDEs, solutions of the Cauchy (initial-value) problem may exist only until a finite moment $t = t_c$, and they cannot be continued afterwards. At $t = t_c$, the solution loses its initial smoothness, and a singularity appears, which causes the blow-up of the solution. For conservative systems where the wavefield develops sharply diverging gradients, this blow-up phenomenon is often called collapse.

Historically, the first example of collapse follows from the so-called Hopf equation: $u_t + uu_x = 0$, which describes the one-dimensional velocity of dust with zero pressure. This equation admits the generic implicit solution $u = F(x - ut)$, where F is determined from the initial velocity profile. For any compact distribution F , there exists a couple of coordinates (x_c, t_c) , at which the spatial derivative of u reaches infinity.

Collapse also occurs in the high-dimensional solutions to the nonlinear Schrödinger (NLS) equation, consisting of a point-singularity that achieves the fate of nonlinear waves undergoing self-focusing (Kelley, 1965). To describe this process, let us consider the NLS equation

$$i\partial_t \psi + \nabla^2 \psi + |\psi|^2 \psi = 0, \quad (1)$$

where t is a time variable and the Laplacian $\nabla^2 = \partial_x^2 + \partial_y^2 + \partial_z^2 + \dots$ accounts for the dispersion of a wave-packet along D orthogonal spatial axes [$\mathbf{r} = (x, y, z, \dots)$]. The wave function ψ evolves from the spatially localized initial datum $\psi(\mathbf{r}, 0) \equiv \psi_0(\mathbf{r})$, assumed to belong to the Hilbert space H^1 with finite norm $\|\psi\|_{H^1} = (\|\psi\|_2^2 + \|\nabla \psi\|_2^2)^{1/2}$, where $\|f\|_p \equiv (\int |f|^p d\mathbf{r})^{1/p}$. Two invariants are associated with ψ , namely, the L^2 norm N (sometimes called mass, power, or number of particles) and the Hamiltonian H :

$$N = \|\psi\|_2^2, \quad H = \|\nabla \psi\|_2^2 - \frac{1}{2} \|\psi\|_4^4. \quad (2)$$

From Equation (1), the following virial equality can be established (Glassey, 1977):

$$Nd_t^2 \langle r^2 \rangle = 4\{2H + (1 - D/2)\|\psi\|_4^4\}, \quad (3)$$

where $\langle r^2 \rangle = \int r^2 |\psi|^2 d\mathbf{r} / N$ denotes the mean-squared radius of the solution ψ . By a double integration in time, Equation (3) shows that, whenever $D \geq 2$, there exist initial conditions for which $\langle r^2 \rangle$ vanishes at finite time, which is the signature of a wave collapse. For finite norms N , the inequality $N \leq (2/D)^2 \langle r^2 \rangle \times \|\nabla \psi\|_2^2$ implies that the gradient norm diverges in collapse regimes. As H is finite, the collapse dynamics makes the L^4 norm $\|\psi\|_4^4$ blow up in turn and $\max |\psi|$ diverges, by virtue of the mean-value theorem $\int |\psi|^4 d\mathbf{r} \leq \max_r |\psi|^2 \times N$. This leads to a finite-time blow-up, at which the solution ψ ceases to exist in H^1 . Blow-up generally occurs before $\langle r^2 \rangle$ reaches zero (Rasmussen & Rypdal, 1986).

While $H < 0$ arises from Equation (3) as a sufficient condition for collapse, sharper requirements can be derived by means of the so-called Sobolev inequality

$$\|\psi\|_4^4 \leq C \|\nabla \psi\|_2^2 \times \|\psi\|_2^{4-D}. \quad (4)$$

- In the critical case $D=2$, this inequality can be used to bound H from below, so that the gradient norm blows up only if N fulfills the constraint $N > N_c$. The best constant in Equation (4) is exactly $C_{\text{best}} = 2/N_c$, and it involves the quantity $N_c = \int \phi_0^2 d\mathbf{r} = 11.68$, where ϕ_0 is the radially symmetric soliton solution of $-\phi_0 + \nabla^2 \phi_0 + \phi_0^3 = 0$ (Weinstein, 1983). N_c provides the minimum power that ψ must necessarily contain at $t=0$ for producing a collapse, justifying the existence of a critical power for the 2-dimensional self-focusing of optical beams in nonlinear Kerr media.
- In the supercritical case $D=3$, a criterion for collapse, sharper than $H < 0$, can be established from a combination of Equations (3) and (4) as $H < N_c^2/N$ for gradient norms initially above $3N_c^2/N$ (Kuznetsov et al., 1995). N_c again corresponds to the mass of the three-dimensional soliton solution ϕ_0 satisfying $-\phi_0 + \nabla^2 \phi_0 + \phi_0^3 = 0$.

Once the collapse is triggered, the solution self-focuses and shrinks isotropically in a self-similar way near the singularity point t_c . It is, thus, convenient to introduce the self-similar substitution:

$$\psi(\mathbf{r}, t) = a^{-\alpha}(\tau) \phi(\xi, \tau) e^{i\lambda\tau - i\beta\xi^2/4}, \quad (5)$$

where $\xi = \mathbf{r}/a(t)$, $\tau(t) \equiv \int_0^t du/a^2(u)$, and $\beta = -a\dot{a}$ (dot indicates differentiation with respect to time). Here, the parameter λ is positive for localization of ϕ . The function $a(t)$ represents the scale length that vanishes as collapse develops, and ϕ converges to an exactly self-similar form $\phi(\xi)$, which no longer

depends explicitly on time $[\partial_\tau \phi \rightarrow 0]$. Inserting (3) into H shows that the right balance between the gradient and L^4 norms requires $\alpha = 1$, in order to preserve the finiteness of the Hamiltonian. With $\alpha = 1$, $N = a^{D-2}(t) \int |\phi|^2 d\xi$ and for radial solutions, Equation (1) transforms to

$$i\partial_\tau \phi + \xi^{1-D} \partial_\xi \xi^{D-1} \partial_\xi \phi + |\phi|^2 \phi + \varepsilon [\xi^2 - \xi_\tau^2] \phi = 0, \quad (6)$$

where $\xi_\tau^2 \equiv \varepsilon^{-1}[\lambda + i\beta(D/2 - 1)]$ is viewed as a turning point, with $\varepsilon \equiv \frac{1}{4}(\beta^2 + \partial_\tau \beta)$. As $a(t) \rightarrow 0$, ϕ can be treated by means of quasi-self-similar techniques (Bergé, 1998). In the limit $\partial_\tau \phi \rightarrow 0$, ε converges to $\beta^2/4$ and the solution ϕ is split into a nonlinear core (ϕ_c) extending in the range $\xi < \xi_\tau$ and a linear tail (ϕ_τ) defined in the complementary spatial domain $\xi > \xi_\tau$, where the nonlinearity vanishes. As a result, the wave function ψ reads near the collapse point:

$$\psi(\mathbf{r}, t) = \frac{e^{i\lambda \int_0^t da/a^2(u)}}{a(t)} \times \left\{ \phi_c\left(\frac{r}{a}, \varepsilon\right) e^{-i\beta r^2/4a^2} \Big|_{0 \leq r < r_\tau} + \frac{C(\beta)}{(r/a)^{1+i\lambda/\beta}} \Big|_{r_\tau < r < r_{\max}} \right\}, \quad (7)$$

where $|C(\beta)|^2$ evolves like $(2/\beta|\xi_\tau|^{D-2})e^{-\lambda\pi/\beta}$, $r_\tau = a(t)|\xi_\tau|$ and $r_{\max}$ bounds the self-similarity domain. The length $a(t)$ is identified from the continuity equation describing the mass exchanges between the core and tail parts of ψ . The dynamics of self-similar collapses then vary with the space dimension number as follows.

- **Strong collapse:** For $D=2$, the size $a(t)$ behaves with a double-logarithmic correction: $a(t) \simeq a_0 \sqrt{t_c - t} / [\ln \ln [1/(t_c - t)]]$, coming from $t_c \simeq \lambda\pi / \ln[t(t)]$ and $\tau(t) \simeq \ln[1/(t_c - t)]$. As $t \rightarrow t_c$, the exponential contribution in tail (5) thus decreases to zero, while the core boundary ξ_τ increases slowly to infinity. Collapse thus takes place with a core solution providing the principal contribution in the wavefunction ψ . N is mainly given by $\int |\phi_c|^2 d\xi$, which relaxes to the critical value $N_c = 11.68$. The mass stays mostly located around the center, which meets the definition of *strong collapse* (Zakharov & Kuznetsov, 1986).
- **Weak collapse:** For $D=3$, β attains a fixed point $\beta_0 \neq 0$, leading to the scaling law $a(t) \simeq a_0(t_c - t)^{1/2}$. The power is no longer preserved self-similarly in space, since $N = a(t) \int |\phi|^2 d\xi$. This integral behaves as $N \simeq N_{\text{core}}(t) + N_{\text{tail}}(t)$, where $N_{\text{core}}(t) \sim a(t)$ vanishes, while $N_{\text{tail}}(t) \simeq 4\pi |C(\beta)|^2 r_{\max}$ contains almost all the initial mass as $a(t) \rightarrow 0$. A 3-D collapse is thus accompanied by an expulsion of particles towards the large-distance domain $r \gg r_\tau(t)$,

which characterizes a *weak collapse*. The solution ψ blows up at the center, where N_{core} becomes zero. Accordingly, ψ extends in the outer domain with the stationary density $r^2 |\psi|^2 \rightarrow |C(\beta_0)|^2 = \text{const}$.

These different collapses can be tested numerically by adding a small nonlinear dissipation term in Equation (1), i.e., by changing ψ_t into $\psi_t + \beta |\psi|^m \psi$ with $\beta \ll 1$ and $m > 1$. For $D=2$, dissipation removes a substantial amount of energy per collapse event, because N remains mostly confined at the center. This leads to a step-wise decrease of N (Kosmatov et al., 1991). In contrast, for $D=3$, nonlinear dissipation cannot remove much energy, the major part of $N \simeq N_{\text{tail}}$ being transferred to large distances. This causes a monotonical decrease of N .

- **Superstrong collapse:** For weak and strong collapses, only the energy captured by the singularity dissipates. A different situation is realized if collapsing solutions can sustain dissipation through power loss into a persistent region of high intensity. Such solutions approach a quasi stationary state, described by $\psi_{rr} + (D-1)\psi_r/r + |\psi|^2 \psi = 0$, in the limit of small $\beta \rightarrow 0$. For instance, when $D=4$, Equation (1) admits the stationary radial state $\psi(r) = B e^{i \ln r / \sqrt{B^2 - 1}} / r$ ($B > 1$), for which the power density $|\psi|^2$ flows into the singularity with a constant energy flux equal to $B^2 \sqrt{B^2 - 1}$. This collapse, which received the adjective of *superstrong*, has been numerically detected at high dimension numbers $D > 3$ (Kosmatov et al., 1991).

So far, the discussion has remained within the realm of the one-wave component NLS equation with a cubic nonlinearity. It is thus worth underlining the following.

- The previous results can be generalized to a power-law nonlinearity, when the cubic term $|\psi|^2 \psi$ of Equation (1) is replaced by $|\psi|^{2n} \psi$ with $n > 1$ (Rasmussen & Rypdal, 1986; Bergé, 1998). Solutions with $D=2/n$ follow the route of a strong collapse, while solutions defined for $D > 2/n$ collapse weakly. Superstrong collapses apply to the dimensional configurations $D > 2 + 1/n$.
- Several NLS equations coupled through their cubic nonlinearities often serve to model the self- and cross-interactions of multiple wave components (or different polarizations) in vector systems. Such systems promote blow-up phenomena, which can be examined by means of the above analytical tools (Bergé, 2001).
- Blow-up may take place in solutions of PDEs other than the NLS equation. For example, investigations of the solutions to the generalized D -dimensional Korteweg–de Vries (KdV) equation

$$q_t + q^n q_x + (\nabla^2 q)_x = 0 \quad (8)$$

suggest that, whereas no collapse occurs for values of the product $nD < 4$, collapsing states can arise and adopt a self-similar shape provided that $nD \geq 4$ (Blaha et al., 1989). The mathematical proof for this statement is presently incomplete.

DIFFERENTIAL GEOMETRY

A *topological manifold of dimension n* is a topological space M that can locally be identified with an open set in $\mathbb{R}^n$; a superscript on the symbol for M is often used to indicate the dimension. For example, a circle is a one-dimensional manifold, denoted S^1 , while a figure-eight is not a manifold. In more detail, M must have a set of *coordinate charts* ϕ_α , each of which is a homeomorphism from an open set $U_\alpha \subset M$ to an open set in $\mathbb{R}^n$, such that every point of M is in the domain of a

chart. If the intersection $U_{\alpha\beta}$ of two domains U_α and U_β is nonempty, then the change of coordinates $\phi_\alpha \circ \phi_\beta^{-1}$ is a continuous map from $\phi_\beta(U_{\alpha\beta})$ to $\phi_\alpha(U_{\alpha\beta})$ with a continuous inverse.

A *differentiable manifold* is a topological manifold M^n equipped with charts such that, on the overlaps, $\phi_\alpha \circ \phi_\beta^{-1}$ is differentiable with a differentiable inverse. (Here, “differentiable” or “smooth” functions are those whose partial derivatives exist and are continuous to all orders; however, for C^k manifolds, the changes of coordinates are only required to be differentiable up to order k .) If $x^1, \dots, x^n$ and $\bar{x}^1, \dots, \bar{x}^n$ are the coordinate functions for two overlapping charts, then the Jacobian determinant $|\partial x^i / \partial \bar{x}^j|$ must be nonzero at each point.

For example, the subset M of $\mathbb{R}^{n+1}$ defined by an equation form $f(x^0, x^1, \dots, x^n) = 0$ is a differentiable manifold if f is a smooth function and at each point $p \in M$, at least one partial derivative (say, $\partial f / \partial x^0$) is nonzero. Then, by the Implicit Function Theorem, the projection from a neighborhood of p (i.e., an open subset of M containing p) onto the $x^1 \dots x^n$ coordinate hyperplane is differentiable with a differentiable inverse. So, the n -dimensional spheres S^n are compact differentiable manifolds. Similarly, the group SL_n of $n \times n$ matrices with determinant one is a noncompact manifold of dimension $n^2 - 1$.

A function $f: M \rightarrow \mathbb{R}$ is smooth if $f \circ \phi$ is smooth for any chart ϕ . More generally, if M^m and N^n are two differentiable manifolds, we say a mapping $F: M \rightarrow N$ is smooth if it is smooth with respect to coordinate charts on both ends, that is, $\psi \circ F \circ \phi^{-1}$ is smooth from $\mathbb{R}^m$ to $\mathbb{R}^n$ for any charts ϕ on M and ψ on N . When $F: M \rightarrow N$ also has a smooth inverse, it is a *diffeomorphism*, and M and N are *diffeomorphic*. For example, the hyperboloid $x^2 + y^2 - z^2 = 1$ is diffeomorphic to the cylinder $x^2 + y^2 = 1$, and any open interval on the real line $\mathbb{R}$ is diffeomorphic to all of $\mathbb{R}$.

Vector Fields and 1-Forms

A *tangent vector* at a point $p \in M^n$ is a linear operator v on smooth functions f defined near p , such that (i) $v(f_1 f_2) = f_1 v(f_2) + f_2 v(f_1)$, and (ii) $v(f_1) = v(f_2)$ if $f_1 = f_2$ on a neighborhood of p (i.e., f_1, f_2 have the same *germ* at p). For example, if $c: \mathbb{R} \rightarrow M$ defines a curve in M such that $c(t) = p$, then we define the tangent vector $c'(t)$ to the curve by $c'(t)(f) := (d/dt)f(c(t))$, where the symbol “:=” indicates a definition. If $v = c'(t)$, then we say that the curve is *tangent* to v at p .

The set of tangent vectors at p form a vector space of dimension n , denoted $T_p M$. If $x^1, \dots, x^n$ are local coordinates near p , then the partial derivative operators $\partial/\partial x^i$ are a basis for $T_p M$. The set of all tangent vectors at all points of M is itself a differentiable manifold of dimension $2n$, since we can adjoin coordinates

$y^1, \dots, y^n$ and locally write all tangent vectors as

$$\mathbf{v} = \sum_{i=1}^n y^i \frac{\partial}{\partial x^i}.$$

This manifold is the *tangent bundle* of M , and is denoted TM .

A *vector field* on M smoothly assigns a tangent vector at each point; in local coordinates, we specify a vector field by giving the y^i as smooth functions of x^i . If f is a smooth function on M and $\mathbf{V}$ is a vector field, then $\mathbf{V}(f)$ is another smooth function.

Given a vector field $\mathbf{V}$ and a point $p \in M$ at which $\mathbf{V} \neq 0$, existence theorems for systems of ODE (e.g., Picard's Theorem) imply that there exist a neighborhood U of p and a one-parameter family of smooth, one-to-one mappings $F_t: U \rightarrow M$, such that for any fixed $q \in U$, the curve $F_t(q)$ is tangent to $\mathbf{V}$ for every t . The F_t 's are called the *flow by vector field* $\mathbf{V}$.

The *Lie bracket* $[V_1, V_2]$ of two vector fields V_1, V_2 is a third vector field defined by

$$[V_1, V_2](f) := V_1(V_2(f)) - V_2(V_1(f)).$$

If y^i and y_j^i are the components of V_1, V_2 in local coordinates, then

$$[V_1, V_2] = \sum_{i,j=1}^n \left(y_1^i \frac{\partial y_2^j}{\partial x^i} - y_2^i \frac{\partial y_1^j}{\partial x^i} \right) \frac{\partial}{\partial x^j}. \quad (1)$$

The vector fields are said to *commute* if $[V_1, V_2]$ is identically zero; then, flow by V_1 commutes with flow by V_2 .

A *differential 1-form* at p is a linear mapping function from $T_p M$ to $\mathbb{R}$. For example, given a differentiable function f defined near p , we define the 1-form df by $df(\mathbf{v}) := \mathbf{v}(f)$ for all $\mathbf{v} \in T_p M$. The vector space of 1-forms at p is denoted $T_p^* M$. Given local coordinates, the differentials $dx^1, \dots, dx^n$, which satisfy $dx^i(\partial/\partial x^j) = \delta_j^i$, are a basis for $T_p^* M$. While tangent vectors generalize directional derivatives in $\mathbb{R}^n$, 1-forms generalize gradients; however, 1-forms cannot be identified with tangent vectors without using some nondegenerate bilinear form on tangent vectors, for example, a Riemannian metric or symplectic form on M .

A *differential 1-form* on M assigns a 1-form at each point; in local coordinates, these appear as

$$\omega = \sum_{i=1}^n z_i dx^i,$$

where the z_i are some smooth functions of the x^i . If $\mathbf{V}$ is a vector field on M , then $\omega(\mathbf{V})$ is a function on M .

Given a smooth mapping $F: M \rightarrow N$, we can transform a tangent vector $\mathbf{v} \in T_p M$ to a tangent vector $F_* \mathbf{v}$ at $F(p)$ by defining

$$F_* \mathbf{v}(f) := \mathbf{v}(f \circ F)$$

for any function $f: N \rightarrow \mathbb{R}$. This is called the *pushforward* of $\mathbf{v}$. We similarly define the pushforward $F_* \mathbf{V}$ of a vector field $\mathbf{V}$ on M . We can also transform a 1-form ω on N to a 1-form $F^* \omega$ on M by defining

$$F^* \omega(\mathbf{v}) := \omega(F_* \mathbf{v})$$

for any tangent vector $\mathbf{v}$ to M . This is called the *pullback* of ω .

If $\mathbf{V}$ is a vector field and F_t is the flow by $\mathbf{V}$, we define the *Lie derivative* of a 1-form ω with respect to $\mathbf{V}$ by

$$\mathcal{L}_V \omega := \left. \frac{d}{dt} \right|_{t=0} F_t^* \omega.$$

If the components of $\mathbf{V}$ and ω in local coordinates are y^i and z_i , respectively, then

$$\mathcal{L}_V \omega = \sum_{i,j=1}^n \left(y^i \frac{\partial z_j}{\partial x^i} - z_i \frac{\partial y^j}{\partial x^i} \right) dx_j. \quad (2)$$

Some useful properties of the Lie derivative are that it obeys the product rule and commutes with d , that is,

$$\begin{aligned} \mathcal{L}_V(fW) &= (\mathcal{L}_V f)W + f \mathcal{L}_V W, \\ \mathcal{L}_V(f\omega) &= f \mathcal{L}_V \omega + (\mathcal{L}_V f)\omega, \\ \mathcal{L}_V(df) &= d(\mathcal{L}_V f), \end{aligned}$$

where we define $\mathcal{L}_V f := \mathbf{V}(f)$ and $\mathcal{L}_V W := [V, W]$. (Note that one can derive (2) using these properties.)

Higher Degree Differential Forms and Topology

A *differential k -form* at p is a multilinear function on k -tuples of vectors in $T_p M$ that is skew-symmetric; that is, its value is multiplied by -1 whenever two adjacent vectors in the k -tuple are exchanged. For example, a 2-form may be constructed from two 1-forms ω^1, ω^2 using the *wedge product*:

$$\omega^1 \wedge \omega^2(\mathbf{v}_1, \mathbf{v}_2) := \omega^1(\mathbf{v}_1)\omega^2(\mathbf{v}_2) - \omega^1(\mathbf{v}_2)\omega^2(\mathbf{v}_1).$$

(Note that this is zero if ω^1 and ω^2 are linearly dependent.) More generally, the wedge product of 1-forms $\omega^1, \dots, \omega^k$ is defined by

$$\begin{aligned} \omega^1 \wedge \dots \wedge \omega^k(\mathbf{v}_1, \dots, \mathbf{v}_k) \\ := \sum_{\sigma} (-1)^\sigma \omega^1(\mathbf{v}_{\sigma(1)}) \omega^2(\mathbf{v}_{\sigma(2)}) \dots \omega^k(\mathbf{v}_{\sigma(k)}), \end{aligned}$$

where the sum is over all permutations σ of $1, 2, \dots, k$ and $(-1)^\sigma$ is the sign of the permutation. On an n -dimensional manifold, the vector space of k -forms

at a point has dimension $\binom{n}{k}$ and is spanned by wedge products of 1-forms; in particular, there are no forms of degree higher than n .

A 2-form may also be constructed from a single 1-form ω by taking the exterior derivative $d\omega$, which satisfies

$$d\omega(V_1, V_2) = V_1(\omega(V_2)) - V_2(\omega(V_1)) - \omega([V_1, V_2]). \quad (3)$$

(Although the right-hand side is defined using vector fields, its value at a point p depends only on the values of V_1, V_2 at p .) The exterior derivative of a k -form is a $(k+1)$ -form; it can be calculated inductively using linearity and the product rule

$$d(\alpha \wedge \beta) = d\alpha \wedge \beta + (-1)^{\text{degree}(\alpha)} \alpha \wedge d\beta.$$

If the exterior derivative of a k -form is identically zero on M , the form is *closed*. If a k -form is an exterior derivative of a $(k-1)$ -form, it is *exact*. An important property of the exterior derivative is that $d(d\alpha) = 0$, i.e., exact forms are closed. The *Poincaré Lemma* asserts that a closed k -form α is *locally* exact; that is, in the vicinity of any given point a $(k-1)$ -form β is defined such that $\alpha = d\beta$. However, not every closed form is *globally* exact (e.g., the 1-form $d\theta$ on S^1). Moreover, the *de Rham Theorem* asserts that the dimension of the vector space of closed k -forms modulo exact k -forms is a topological invariant of M ; that is, two manifolds cannot be homeomorphic (or diffeomorphic) unless these dimensions, known as the *Betti numbers*, match up. (For example, the Euler characteristic is determined by the Betti numbers.)

DIFFUSION

When a small drop of ink is poured onto a soft gel, the ink molecules disperse through by diffusion. Similarly, the spread of heat through a medium can also be a diffusive process (called heat conduction). Many other applications of diffusion arise in biology, combustion, economics, chemical engineering, and geophysics, among other fields.

Mathematically, the diffusion equation takes the form (Crank, 1975)

$$u_t = \Delta u, \quad (1)$$

where $u = u(x, t)$ is the state variable, representing, for example, the density of concentration of some substance, at time $t \geq 0$ and position x in R^n , where Δu denotes the Laplacian of u with respect to the space variable x . Equation (1) is an example of a parabolic equation of evolution. If it holds for all x in R^n , then the problem is fully specified once appropriate initial conditions

$$u(x, 0) = u_0(x) \quad (2)$$

are known. If Equation (1) holds in a limited domain $\Omega \subset R^n$, then some boundary conditions must be imposed on u at $\partial\Omega$ that are compatible with the physical situation.

The diffusion equation can be viewed as a balance law (Grindrod, 1996). Let $Q(x, t)$ be the net creation rate of particles at $x \in \Gamma \subset \Omega$ and time t , and let $J(x, t)$ be the flux density. For any unit vector $n \in R^n$, the scalar product $J \cdot n$ is the net rate at which particles cross a unit area in a plane perpendicular to n (take the plus sign in the direction of n). Assuming that the rate of change of mass in Ω is due to particle creation or degradation inside Γ and the inflow and the outflow of particles through the boundary $\partial\Gamma$, we have

$$\frac{d}{dt} \int_{\Gamma} u \, dx = - \int_{\partial\Gamma} J \cdot n \, dS + \int_{\Gamma} Q \, dx, \quad (3)$$

where $\int_{\Gamma} u \, dx$ denotes the population mass in Γ . If the solution is smooth enough, then applying the divergence theorem to the right-hand side in (3) gives

$$\frac{d}{dt} \int_{\Gamma} u \, dx = \int_{\Gamma} \nabla \cdot J \, dS + \int_{\Gamma} Q \, dx. \quad (4)$$

As Γ was arbitrary in Ω , Equation (4) implies that

$$u_t = -\nabla \cdot J + Q \quad (5)$$

at every point in Ω , which is the required balance law.

In practice, depending on the process studied, one must specify the flux J and the source term Q . For example, in combustion or in chemistry, one uses Fick's law:

$$J = -D\nabla u. \quad (6)$$

Here $D > 0$ is a constant called diffusivity with physical units of $m^2 s^{-1}$. The minus sign in (6) accounts for the fact that the particles are transported from high to low densities. Using (6) in (5) gives the usual reaction-diffusion equation

$$u_t = D\Delta u + Q(x, t, u, \dots). \quad (7)$$

A heuristic derivation of the diffusion equation (1) involves the notion of a random walk. Consider a one-dimensional (1-d) random walker that at each time step t_i hops from its position x_n one unit to the left or right, $x_{n\pm 1}$. The change in probability $p(x_n, t_i)$ to find the walker at x_n at t_i is equal to the sum of probabilities

for it to hop into the point minus the sum of probabilities to hop off the point:

$$\begin{aligned} p(x_n, t_i) - p(x_n, t_{i-1}) \\ = \frac{1}{2} (p(x_{n+1}, t_{i-1}) + p(x_{n-1}, t_{i-1})) - p(x_n, t_{i-1}). \end{aligned} \quad (8)$$

Introducing the space and time scales of the motion, this equation can be rearranged as

$$\begin{aligned} \frac{p(x_n, t_i) - p(x_n, t_{i-1})}{\delta_t} \\ = \frac{\delta_x^2}{2\delta_t} \left[\frac{p(x_{n-1}, t_{i-1}) - 2p(x_n, t_{i-1}) + p(x_{n+1}, t_{i-1})}{\delta_x^2} \right]. \end{aligned} \quad (9)$$

Denoting $D = \delta_x^2/2\delta_t$, Equation (9) becomes a discrete approximation of Equation (1), and by taking the limit as $\delta_t, \delta_x \rightarrow 0$, keeping D finite, we recover Equation (1).

A rigorous derivation of the diffusion equation is obtained via stochastic calculus. The motion of individual particles is described by stochastic differential equations with the positions of the particles being modeled as random variables in R^n . The global behavior depends on the type of stochastic process governing the motion of the particles. Typically, one describes this in terms of the probability distribution of the random variable. In many cases, one finds that all its moments of order higher than 2 vanish. Consequently, the distribution of the population density, u , satisfies the second-order Fokker–Planck (or Kolmogorov’s forward equation) (Øksendal, 2000)

$$u_t = \nabla(D(x, t)u) - \nabla(C(x, t)u). \quad (10)$$

Equation (10) is a diffusion equation with a nonconstant, inhomogeneous diffusivity and convective term. It often arises for particles whose individual speeds are random deviations from some externally applied convection velocity. Examples arise in fluid flow and in biology (dispersals of population dispersals, e.g. chemotaxis), among other fields.

Particularly important cases are when the diffusivity depends on the population density such as in biology or ecology (Aronson & Weinberger, 1975). For example, insect dispersal models use the fact that the rate of spread of the population is increased at higher insect density. This is usually modeled with an equation of the form

$$u_t = \Delta(D(u)\nabla u) + f(u), \quad (11)$$

where typically $D(u) = D_0u^m$, $m > 0$ (Okubo & Levin, 2001; Murray, 2002). Density-dependent diffusion equations appear in many other fields. In physics, impurities are diffused into semiconductor materials (in the processing of silicon-based electronic devices)

Figure 1. (a) Linear diffusion solutions of Equation (13). (b) Nonlinear diffusion solutions of Equation (14).

so the diffusivity is a function of the density of the semiconductor. Other examples include models of crystal growth, porous media, magnetic flux vortices in superconductors, surface reactions, and so on.

The behavior of the solution to Equation (1) is well understood. If Q is linear in u , then the solution is found by Fourier transform or eigenfunction-expansion techniques. For example, the linear diffusion equation

$$u_t = \Delta u + u \quad (12)$$

with the initial condition $u(x, 0) = \delta(x)$ (Dirac’s delta function) has, in (1-d), the fundamental solution

$$u(x, t) = \frac{1}{2\sqrt{\pi t}} \exp\left(-t - \frac{x^2}{4t}\right), \quad t > 0. \quad (13)$$

Figure 1a illustrates the behavior of Equation (13) as a function of x for various times. Due to the linear source term, the solution grows exponentially (is unbounded). Another feature of solution (13) is the “paradox of infinite speed propagation.” For all $x \neq 0$, $u(x, 0) = 0$, but $u(x, t) > 0$ for all $t > 0$. However, the diffusion equation describes well the global behavior of mass, as it can be easily verified that the center of mass does propagate with a finite speed.

The behavior of solutions of Equation (7) changes dramatically if Q is no longer linear in u . Consider the typical nonlinear autonomous form now called the Fisher–KPP equation and first investigated by Kolmogorov, Petrovsky, and Piscounoff (1937) and,

separately, by Fisher (1937) to model the process of genetic diffusion:

$$u_t = \Delta u + u(1 - u). \quad (14)$$

The only solution evolving from a positive compactly supported initial data is always bounded and propagates in the form of a traveling wave with constant speed $v = 2$, see Figure 1b for an illustration. This is due to the combined action of diffusion and local nonlinearity and has been used in many models applied in biology (genetics, ecology, population dynamics, etc.), chemistry, combustion, economics, physics, etc. The equation similar to (14) but with a cubic nonlinearity (bistable model) instead of the quadratic was proposed in 1938 as a model for a flame front by Zeldovich and Frank-Kamenetsky (1938).

DIMENSIONAL ANALYSIS

The dimensions of quantities in any equation (in physics these are mass, length, time, charge, temperature, angle, and so on) must be the same on both sides; otherwise an equality would be violated by changing units. From such reasoning, it is often possible to derive valuable insights without delving into mechanisms. This “dimensional analysis” is an old idea; Lord Rayleigh (John William Strutt), an early vigorous exponent of the method, called it the “principle of similitude,”

Figure 1. A right triangle is broken into two smaller right triangles of the same proportions.

which he extolled in the following terms (Rayleigh, 1915): “It happens not infrequently that results in the form of ‘laws’ are put forward as novelties on the basis of elaborate experiments, which might have been predicted a priori after a few minutes’ consideration.”

The principle was familiar to Galileo, Newton, Fourier, Reynolds, and Maxwell, and was widely used in engineering around 1900. Edgar Buckingham formalized it in what is now called the Pi (for “product”) Theorem, that any functional relation among N quantities represented by real numbers and collectively involving $U < N$ basic units can be rewritten as a dimensionless, constant function of $N - U$ dimensionless, multiplicative combinations of those variables (Buckingham, 1914). Unless N and U are trivially small, some systematic procedure is helpful for finding all possible ways of combining variables into dimensionless constants (Birkhoff, 1950; Coyle & Ballico-Lay, 1984).

Interestingly, there have been attempts to discover the laws of economics and finance by similar procedures, starting of course from a different list of fundamental units (DeJong, 1967).

As most articles on dimensional analysis expound abstract principles, two examples are presented here, one drawn from the ancient roots of mathematics and one from the nonlinear physics of shock waves.

Pythagorean Theorem

The area of a right triangle is uniquely determined by the length of the “long” side and one of the other (“wrong”) angles. Area is some universal function of Long and Angle, let us say the smaller Angle, dotted in Figure 1. Do we have to figure out exactly what function? Maybe not. We know Area has to be proportional to Long² to make the dimensions come out right, and the other factor must be some dimensionless function of the dimensionless Angle (or equivalently of the ratio between the two shorter sides). Break this triangle into two smaller ones of exactly the same shape by constructing a perpendicular from the right angle to the Long side. Call the two areas Area A and Area B. So Area = Area A + Area B.

Each of these similar triangles has for its own long side one of the big triangle’s shorter sides,

and all the angles are the same as in the big one. Thus $\text{Long}^2 f(\text{Angle}) = \text{ShortA}^2 f(\text{Angle}) + \text{ShortB}^2 f(\text{Angle})$, where Angle means the dotted smaller angle, which is the same in all three cases. So unless $f(\text{Angle}) = 0$ (i.e., unless the areas are all 0 anyhow), then

$$\text{Long}^2 = \text{ShortA}^2 + \text{ShortB}^2. \tag{1}$$

This is the theorem attributed to Pythagoras. We obtained it by merely insisting on dimensional consistency (Goldenfeld, 1992).

Atomic Explosions

From any big explosion in air, shock waves propagate outwards, slowing as the hemisphere of destruction expands. How fast does the hemisphere expand? You might think that an answer to this question necessarily involves a complex variety of considerations about sound, chemistry, thermal physics, and so on. Indeed it does, but let us consider an atomic explosion from the perspective of dimensional analysis.

Suppose the results are pretty much the same for any blast of the same total energy. If that were so, how could the expansion of the shock—its distance from ground zero (R) as a function of time (t)—depend on the energy (E) of the blast?

Let us denote the unit of length by the symbol L and the unit of time by the symbol T . (Thus L might be meters and T seconds.) Then energy (which is mass times velocity squared) has units (ML^2T^{-2}) , where M denotes the unit of mass.

Since no combination of the three factors R , T , and E is unitless, we need to include another factor that involves mass. Such a factor is the air density, ρ . This factor is clearly important because without air there would be no shock wave but only bomb parts flying at fixed speeds through the vacuum of space. So throw ρ into the stew with units ML^{-3} . How to relate these four quantities (R , t , E , and ρ) to obtain a unitless result?

From the Pi Theorem, there is only one unitless combination of our four quantities (R , t , E , and ρ) that are expressed in terms of three basic units (L , t , and M). Thus,

$$\frac{R^5 \rho}{t^2 E} = a, \tag{2}$$

where a is a dimensionless number that Geoffrey Taylor estimated (in 1941) to be 0.926 (Taylor, 1950a).

In 1949, Taylor verified his analysis by plotting the log of R (in meters) against the log of t (in seconds) for the first atomic explosion—the Trinity blast of 16 July 1945 in Alamogordo, New Mexico. According to Equation (2), log R versus log t should be a straight line with a dimensionless slope $\frac{2}{5}$. Except for the first point at 0.1 ms, the log-log plot in Figure 2 is indeed close to

Figure 2. A log-log plot of the expansion of the Trinity fireball. From the origin of the blast, a hemispherical shock of radius R expands as a function of t during the first 62 ms. (The inset shows is a photograph of the blast at 15 ms, and the data are from Taylor, 1950b.)

a straight line with slope $\frac{2}{5}$. In dimensional terms,

$$\frac{R^5}{t^2} = 6 \times 10^{13} \text{ m}^5 \text{ s}^{-2} \tag{3}$$

to an experimental uncertainty of about 10%. Because a and ρ are known, the data in Figure 2 reveal the blast energy, which Taylor computed to be the equivalent of about 20 ktons of TNT (Taylor, 1950b).

In 1947, several of the photographs upon which Figure 2 is based were published by *Life*, a popular magazine of the time. Using these data, assuming $a = 1$, and taking $\rho = 1.25 \text{ kg m}^{-3}$, Equations (2) and (3) imply a blast energy of $8.4 \times 10^{10} \text{ kg m}^2 \text{ s}^{-2}$ (or joules), which is equivalent to about 20 ktons of TNT. It may be presumed that interested parties made this simple estimate without delay.

Although these two examples may seem like magic, dimensional analysis has some limitations (Rayleigh, 1915). For example, this approach is useless in the absence of clear functional relations among mathematical quantities. Furthermore, one may doubt that the list of dimensioned variables presumed to be relevant is complete and does not include superfluous items. Finally, the desired relations may be unknown functions of dimensionless combinations of the pertinent variables.

DIMENSIONS

The classical, integer-valued definition of dimension (see Hurewicz & Wallman, 1941) is defined inductively: the empty set has dimension -1 , and a set has dimension n if n is the smallest integer such that every point has arbitrarily small neighborhoods whose boundaries have dimension less than n . This gives the “right” answer for smooth curves and surfaces, whose dimension we know intuitively.

In order to describe more accurately the complicated fractal sets that arise in nonlinear dynamics, we need to introduce more subtle definitions. Surprisingly, there are several generalizations of dimensions that still assign the intuitively correct dimensions to the above-noted well-behaved sets, and we recall two of them here.

The first of these is the “box-counting” dimension, also known as the Minkowski dimension, the fractal dimension, the entropy dimension, the capacity dimension, and the limit capacity: a litany of names that testifies to its popularity. For a subset X of $\mathbb{R}^n$, take a fixed array of boxes of side δ , and count the number $N_\delta(X)$ of these boxes that intersect with X . If $N_\delta(X) \sim \delta^{-d}$ as $\delta \rightarrow 0$, then X has box-counting dimension d . This can be made mathematically precise by defining

$$d_{\text{box}}(X) = \limsup_{\delta \rightarrow 0} \frac{\log N_\delta(X)}{-\log \delta}. \quad (1)$$

(For alternative definitions that give the same quantity see Falconer (1990).) While the box-counting dimension is simple to define, it is not without problems. For example, the set $S = \{0\} \cup \{1/n : n = 1, 2, \dots\}$, an unlikely candidate for a fractal, has box-counting dimension $\frac{1}{2}$. We now introduce another widely used definition of dimension that does not suffer from this anomaly.

We could try to define a notion of the “ d -dimensional volume” of X as the limit of $N_\delta(X)\delta^d$ as $\delta \rightarrow 0$, but such a definition does not even agree with the standard definition of volume (Lebesgue measure) when d is an integer. Instead, the proper generalization of Lebesgue

measure to non-integer dimensions is d -dimensional Hausdorff measure. Essentially, we cover a set $X \subset \mathbb{R}^n$ by a collection of balls of radii $r_i \leq \delta$, and then let $\mathcal{H}^d(X)$ be the limit of $\sum r_i^d$ as δ tends to zero. More precisely, we define

$$\mathcal{H}^d(X) = \liminf_{\delta \rightarrow 0} \left\{ \sum_i r_i^d : r_i \leq \delta \text{ and } X \subseteq \bigcup_i B_r(x_i) \right\}$$

(the notation $B_r(x)$ denotes an open ball centered at x of radius r). The resulting measure is proportional to Lebesgue measure when d is an integer. The “Hausdorff dimension” of X is the smallest value of d for which $\mathcal{H}^d(X)$ is finite,

$$d_H(X) = \inf\{d > 0 : \mathcal{H}^d(X) < \infty\}.$$

Since $\mu_d(X, \delta) \leq N_\delta(X)\delta^d$, we always have $d_H(X) \leq d_{\text{box}}(X)$ (and this inequality can be strict: the set S defined above has zero Hausdorff dimension). While harder to estimate in practice, the Hausdorff dimension is easier to deal with theoretically.

If we want to estimate the dimension of the attractor $\mathcal{A}$ of a dynamical system, it is useful to have a method based on dynamical quantities. In 1980, Douady & Oesterlé showed how to obtain a bound on $d_H(\mathcal{A})$, the dimension of the attractor of an iterated C^1 map f on $\mathbb{R}^n$. Denote by $Df(x)$ the matrix of partial derivatives of f , i.e., $[Df]_{ij} = \partial f_i / \partial x_j$, and let $\lambda_1(x) \geq \lambda_2(x) \geq \dots \geq \lambda_n(x)$ be the logarithms of the eigenvalues of $[Df(x)^T Df(x)]^{1/2}$. Now set

$$d(x) = j + \frac{\lambda_1(x) + \dots + \lambda_j(x)}{|\lambda_{j+1}(x)|}, \quad (2)$$

where j is the largest integer for which $\lambda_1(x) + \dots + \lambda_j(x) \geq 0$ (note that $j \leq d(x) < j+1$). If $d > d(x)$, then any infinitesimal d -volume near x is contracted under the application of f , so

$$d_H(\mathcal{A}) \leq \sup_{x \in \mathcal{A}} d(x). \quad (3)$$

Hunt (1996) showed that the right-hand side of (3) also bounds $d_{\text{box}}(\mathcal{A})$. (A similar approach also works for the attractors of flows by taking f to be the time T map, for some suitable T . Constantin & Foias (1985) have proved a version of (3) for the attractors of infinite-dimensional dynamical systems.)

However, the box-counting and Hausdorff dimensions give equal weighting to all points in the attractor, while it is possible to have regions of the attractor that are visited very rarely. In such a situation, it can be more natural to consider invariant measures rather than attractors. As a (canonical) example of such a measure, suppose that $f : \mathbb{R}^n \rightarrow \mathbb{R}^n$ generates a dynamical system on $\mathbb{R}^n$. Then for any set X , we can define

$$\mu(X) = \lim_{m \rightarrow \infty} \frac{1}{m} \text{card}\{k : f^k(x) \in X, 1 \leq k \leq m\},$$

where x is a point in the basin of attraction of $\mathcal{A}$. The quantity $\mu(X)$ is the proportion of time spent in X by a “typical trajectory” on the attractor.

There are various ways of defining the dimension of a measure μ . We could define the Hausdorff/box-counting dimension of μ to be the dimension of its support,

$$d_{\text{box/H}}(\mu) = \inf\{d_{\text{box/H}}(E) : \mu(E) = 1\},$$

but this still discounts the dynamical information contained in μ . Kaplan & Yorke (1979) defined the *Lyapunov dimension* of μ , $d_L(\mu)$, precisely as in (2), but replacing $\lambda_j(x)$ by the Lyapunov exponents associated with μ (the asymptotic growth rates of infinitesimal displacements about trajectories through μ -almost every choice of initial condition). In 1981, Ledrappier showed that for a very general class of dynamical systems, $d_H(\mu) \leq d_L(\mu)$ (the inequality can be strict), while

$$d_{\text{box}}(\mathcal{A}) \leq \sup_{\text{all invariant ergodic } \mu} d_L(\mu).$$

(Kaplan & Yorke had originally conjectured that $d_{\text{box}}(\mathcal{A}) = d_L(\mu)$.)

We now give two definitions of dimension that take into account the spatial structure of μ . The correlation at scale δ is defined by

$$C(\delta) = \int_{X \times X: |x-y| \leq \delta} d\mu(x) d\mu(y),$$

which gives the probability that two points chosen according to the probability measure μ lie within δ of each other. If $C(\delta) \sim \delta^d$ as $\delta \rightarrow 0$, then d is the *correlation dimension* $d_{\text{corr}}(\mu)$. This was introduced by Grassberger & Procaccia (1983), who demonstrated that this quantity is particularly suited to numerical calculation.

Alternatively, define the “ δ -entropy” $K_\delta(\mu) = -\sum_i \mu(B_i) \ln \mu(B_i)$, where $\{B_i\}$ is an array of boxes of side δ ; the *information dimension* is given by

$$d_{\text{inf}}(\mu) = \lim_{\delta \rightarrow 0} \frac{K_\delta(\mu)}{-\log \delta}.$$

(Ruelle (1989) refers to $d_H(\mu)$ as the “information dimension” of μ : this should serve to emphasize how important it is when discussing dimensions to be explicit about the definition.)

Three of these dimensions occur as part of a scale of dimension-like quantities (see Grassberger, 1983). If B_i is an array of boxes of side δ , set

$$K_\delta(q) = \frac{1}{1-q} \log \sum_i \mu(B_i)^q$$

(“the Renyi q entropy”). Note that $K_\delta(0) = \log N_\delta(\text{supp } \mu)$,

$$\lim_{q \rightarrow 1} K_\delta(q) = -\sum_i \mu(B_i) \ln \mu(B_i) = K_\delta(\mu)$$

and that since $C(\delta) \leq \sum_i \mu(B_i)^2 \leq C(\delta\sqrt{n})$, we have $\log C(\delta) \leq K_\delta(2) \leq \log C(\delta\sqrt{n})$. Now define the *Renyi dimensions* $D_q(\mu)$ by

$$D_q(\mu) = \lim_{\delta \rightarrow 0} \frac{K_\delta(q)}{-\log \delta}.$$

Then $D_0(\mu) = d_{\text{box}}(\mu)$, $D_1(\mu) = d_{\text{inf}}(\mu)$, and $D_2(\mu) = d_{\text{corr}}(\mu)$. Since D_q is non-increasing in q , we have in particular $d_{\text{corr}}(\mu) \leq d_{\text{inf}}(\mu) \leq d_{\text{box}}(\mu)$.

The Renyi dimensions are similar to quantities used to define the “multi-fractal spectrum.” The theory relates the numbers $\tau(q) = (1-q)D_q$ to the frequency of various scaling behaviors about points on a fractal set: roughly, if for some small ε the number of δ -mesh cubes B_i with

$$\delta^{\alpha+\varepsilon} \leq \mu(B_i) < \delta^\alpha$$

scales like $\delta^{-f(\alpha)}$, then

$$f(\alpha(q)) = \tau(q) + q\alpha(q),$$

where $q = f'(\alpha(q))$. The curve $f(\alpha)$ is the multi-fractal spectrum of the measure μ . (As remarked by Falconer (1990), the tempting interpretation of the “fractal spectrum” as the dimension of sets of points x where $\mu(B_\delta(x)) \sim \delta^\alpha$ is incorrect: typically the dimension of such sets will be zero or the same as that of the whole space, see Genyuk (1997/98).) Although these ideas have proved useful in the theory of turbulence (e.g. Frisch, 1995), their mathematical foundations have still to be fully resolved.

DIODES

Many of the desirable features of a wide variety of solid-state electronic devices are based on nonlinear current-voltage characteristics. These involve situations where a sufficiently high bias is applied to the device so that it either switches from one conductive state to another or oscillates between different conductive states.

A two-terminal electronic device is called a diode. In general, the current I through a diode depends upon the polarity of the applied voltage U and exhibits a nonlinear voltage dependence. This includes the important special case of a rectifier diode that conducts the current for one polarity of voltage and blocks it for the other. A rectifier can be realized by a p–n junction (a semiconductor that is p-doped on one side and n-doped on the other side), and it can be described approximately by the current-voltage characteristic

$$I = I_s \left(e^{eU/k_B T} - 1 \right), \quad (1)$$

where I_s is the saturation current for reverse bias $U < 0$, k_B is Boltzmann's constant, and T is the temperature (Figure 1a). For forward bias (positive voltage applied to the p side), the majority carriers (holes from the p side and electrons from the n side) flow towards the junction where they recombine, while for reverse bias they are pulled away from the junction.

The Schottky diode is a rectifier diode, which consists of a metal-semiconductor contact. Interface states and to a small degree the difference in work functions between the metal and the semiconductor give rise to a potential barrier (Schottky barrier) and depletion of majority carriers in the barrier region for reverse bias. The current-voltage characteristic is similar to Equation (1).

Depending upon bias conditions, doping profiles, and device geometry, various other terminal functions of diodes are possible, which involve nonlinear behavior of the conductivity, the capacitance, and the inductance of the device.

The Zener diode is a p–n junction that exhibits a sharp increase in the magnitude of the current at a certain well-controlled reverse bias (Figure 1b). Depending upon the specific device structure, it is either due to avalanche breakdown (multiplication of carriers by impact ionization occurring at high voltage) or due to tunneling across the bandgap (occurring at lower voltage). It is used to stabilize and limit the dc voltage in

Figure 1. Typical nonlinear current-voltage characteristics of diodes. (a) p–n diode, (b) Zener diode, (c) Tunnel diode, (d) p–i–n diode (schematic).

circuits, utilizing the property that the current can vary over a large range at the breakdown threshold without noticeable change in voltage.

A class of diodes exhibits a nonmonotonic dependence of the current I upon voltage U . Negative differential conductance $dI/dU < 0$ can arise due to various mechanisms and may result in self-generated oscillations and complex self-organized spatiotemporal patterns. A famous example is the Esaki tunnel diode (Figure 1c) that, in its original version, consists of a heavily doped p–n junction. In thermal equilibrium, the Fermi level lies within the conduction band on the n side and within the valence band on the p side. When a small forward bias is applied, electrons can tunnel from the n- to the p-side where they find empty states in the valence band. With increasing bias, the filled conduction band states on the n side move up, and the overlap with empty states in the valence band decreases; consequently, the tunneling current decreases, and $dI/dU < 0$. With a further increase of the bias, diffusion of the electrons over the barrier sets in as in a normal p–n junction, and the current increases again.

Modern variants of the tunnel diode are double-barrier resonant tunneling structures and superlattices that consist of alternating layers of different semiconductor materials (heterostructures) forming potential barriers and quantum wells on length scales of a few nanometers. The current density across the barrier between two wells is maximum if there is maximum overlap between the occupied states in one well and the available unoccupied states in the other, that is, if the energies are in resonance. For low bias, equivalent levels in adjacent wells are approximately in resonance, while for higher bias the ground energy level in one quantum well becomes aligned with the second level in the neighboring well. Thus, resonant tunneling produces an $I(U)$ characteristic similar to Figure 1c. High-frequency

oscillations up to 150 GHz can be generated in resonant tunneling structures and superlattices.

Gunn diodes are used to generate and amplify microwaves at frequencies typically beyond 1 GHz (these devices are called “diodes” because they are two-terminal devices, but no p–n junction is involved). The mechanism is based upon field-induced intervalley transfer of electrons from a high- to a low-mobility valley in the conduction band, and the manifestation of the current instability (oscillations or switching) is determined primarily by the cathode contact boundary condition. Traveling high-field domains (Gunn domains), which show up as transit time oscillations, represent an important mode of operation.

Multilayered structures with alternating p- and n-doping represent another class of diodes that exhibit negative differential conductance, high-power microwave oscillations well above 30 GHz, and complex spatiotemporal current density patterns. Starting from the basic $n^+ - p - i - p^+$ structure, where “+” denotes high doping and i is an intrinsic (undoped) layer, various modifications like IMPATT (impact ionization avalanche transit time) diodes, TRAPATT (trapped plasma avalanche-triggered transit) diodes, p–i–n diodes (with double injection of electrons and holes), or $n^+p^+np^-p^+$ devices, where “–” denotes low doping, have been studied. These structures typically display bistability and switching from a low- to a high-conductivity state where carrier multiplication and avalanche breakdown set in (Figure 1d). Negative differential conductance is also exhibited by multilayer systems composed of layers of different semiconductor materials (heterojunctions) like the heterostructure hot electron diode or real-space transfer devices.

A p–n diode may also be operated as a nonlinear capacitor. As the depletion-layer width increases with increasing reverse bias, its capacitance decreases in a controlled way depending upon the doping profile. This effect is used in varactor (*variable reactor*) diodes to tune the capacitance and for parametric amplification. State-of-the-art developments include studies on p–n diodes with embedded quantum dot nanostructures, which strongly exhibit nonlinear capacitance-voltage characteristics as signatures of the charging of these quantum dots.

Nonlinear inductors represent another class of two-terminal devices. A Josephson junction consists of two superconductors separated by a thin nonsuperconducting region. The tunneling of superconducting electron pairs produces a current at zero voltage called the Josephson current. Switching can be obtained from this state to a voltage state by either current overdrive or a magnetic field. The dynamic response of the Josephson junction can be represented by an equivalent circuit with an intrinsic field-dependent inductance.

DISCRETE BREATHERS

The study of dynamical nontopological localization in translational invariant nonlinear Hamiltonian lattices has experienced considerable development during the late 1990s (Sievers & Page, 1995; Aubry, 1997; Flach & Willis, 1998). The discreteness of space—that is, the use of a spatial lattice—is crucial in order to provide structural stability for spatially localized excitations. Spatial discreteness is a very common situation for various applications from, for example, solid-state physics.

To make things precise, consider a d -dimensional hypercubic spatial lattice with discrete translational invariance. Each lattice site is labeled by a d -dimensional vector l with integer components. To each lattice site we associate one pair of canonically conjugated coordinates and momenta X_l, P_l that are real functions of time t . Let us then define some Hamiltonian H being a function of all coordinates and momenta and further require that H has the same symmetries as the lattice. The dynamical evolution of the system is given by the usual Hamiltonian equations of motion. Without loss of generality, let us consider that H is a nonnegative function and that $H=0$ for $X_l = P_l = 0$ (for all l 's). We call this state the classical ground state. Generalizations to other lattices and larger numbers of degrees of freedom per lattice site are straightforward.

When linearizing the equations of motion around $H=0$, we obtain an eigenvalue problem. Due to translational invariance the eigenvectors will be spatially extended plane waves, and the eigenvalues Ω_q (frequencies) form a phonon spectrum, that is, Ω_q is a function of the wave vector q . Due to the translation symmetry of the Hamiltonian, Ω_q will be periodic in

q . Moreover, the phonon spectrum will be bounded, that is, $|\Omega_q| \leq \Omega_{\max}$. Depending on the presence or absence of Goldstone modes Ω_q might be gapless (zero belongs to the spectrum, spectrum is acoustic) or exhibit a gap ($|\Omega_q| \geq \Omega_{\min}$, spectrum is optical). Increasing the number of degrees of freedom per lattice site induces several branches in Ω_q with possible gaps between them.

Let us search for spatially localized time periodic solutions of the full nonlinear equations of motion, that is, $X_l|_{l \rightarrow \infty} \rightarrow 0$, and

$$X_l(t) = X_l(t + T_b) + \lambda k_l, P_l(t) = P_l(t + T_b), \quad (1)$$

with k_l being integers and λ a spatial period (the equations of motion should be invariant under shifts of X_l by multiples of λ if applicable.) These solutions are called discrete breathers. If $k_l \neq 0$ for a finite subset of lattice sites, the solutions are sometimes called "rotobreathers."

If a solution exists, we can expand it into a Fourier series in time, that is, $X_l(t) = \sum_k A_{kl} e^{ik\omega_b t}$ ($\omega_b = 2\pi/T_b$). Spatial localization implies $A_{kl} \rightarrow \infty \rightarrow 0$. Inserting these series into the equations of motion results in a set of coupled algebraic equations for the Fourier amplitudes (Flach & Willis, 1998). Consider the spatial tail of the solution where all Fourier amplitudes are small and should further decay to zero with growing distance from the excitation center. Since all amplitudes are small, the equations of motion can be linearized. This procedure decouples the interaction in k -space, and we obtain for each k a linear equation for A_{kl} with coupling over l . This equation will contain $k\omega_b$ as a parameter. It will, in fact, be identical to the above-discussed equation linearized around $H = 0$, and it will contain $k\omega_b$ instead of Ω_q (Flach & Willis, 1998). If $k\omega_b = \Omega_q$, the corresponding amplitude A_{kl} will not decay in space, instead it will oscillate. To obtain localization, we arrive at the nonresonance condition (Flach & Willis, 1998)

$$k\omega_b \neq \Omega_q. \quad (2)$$

This condition has to be fulfilled for all integer k . For an optical spectrum Ω_q , frequency ranges for ω_b exist, which satisfy this condition. For acoustic spectra, $k = 0$ has to be considered separately (Flach et al., 1997).

The nonresonance condition is only a necessary condition for generic occurrence of discrete breathers. More detailed analysis shows that breathers being periodic orbits bifurcate from band edge plane waves (Flach, 1996). The condition for this bifurcation is an inequality involving parameters of expansion of H around $H = 0$ (Flach, 1996). Rigorous existence proofs for weakly coupled anharmonic oscillators use, for example, the implicit function theorem (MacKay & Aubry, 1994).

Discrete breathers (periodic orbits) appear generically as one-parameter families of periodic orbits. The

parameter of the family can be, for example, the frequency (or energy, action, etc.). Note that we do not need any topological requirement on H (no energy barriers). Indeed, breather families possess limits where the breather delocalizes and its amplitude becomes zero.

With the help of the nonresonance conditions, we can exclude the generic existence of spatially localized solutions that are quasi-periodic in time. Indeed, in the simplest case, we would have to satisfy a nonresonance condition $k_1\omega_1 + k_2\omega_2 \neq \Omega_q$ for ω_1/ω_2 being irrational and all possible pairs of integers k_1, k_2 . This is impossible (Flach, 1994).

The nonresonance condition also explains why breather solutions are nongeneric for nonlinear Hamiltonian field equations, since Ω_q becomes unbounded for a spatially continuous system. Consequently, generically an infinite number of unavoidable resonances destroys the breather existence there.

Note that in many cases breathers can be easily excited by choosing some localized perturbation of the lattice system. Integrating numerically the equations of motion, we find that the energy distribution is not delocalizing but stays essentially localized over several orders of magnitude of the characteristic phonon periods. These numerical results clearly show that breathers are not only interesting solutions but can be rather typical and robust depending on the system's parameters.

Note that breathers can also exist for autonomous forced damped systems (MacKay & Sepulchre, 1998). In these systems, contrary to the Hamiltonian ones, breather periodic orbits do not come in one-parameter families of the frequency ω_b , but correspond to limit cycle attractors that are isolated in the system's phase space.

DISCRETE NONLINEAR SCHRÖDINGER EQUATIONS

With a fairly generous definition, a discrete nonlinear Schrödinger (DNLS) equation is any equation that can be obtained from a nonlinear Schrödinger (NLS) equation of general form

$$i \frac{\partial \phi}{\partial t} + \Delta \phi + f(|\phi|^2) \phi = 0, \quad (1)$$

by employing some finite-difference approximation to the operators acting on the space-time-dependent continuous field $\phi(\mathbf{r}; t)$. In (1), $\Delta = \nabla^2$ is the Laplace operator acting in one, two, or three spatial dimensions, and f is a quite general function that, for most purposes, is taken to be differentiable and with $f(0) = 0$. In the most well-known case of cubic nonlinearity, $f(|\phi|^2) = \gamma|\phi|^2$, Equation (1) is often referred to as *the* NLS equation, and is integrable with the inverse scattering method if the number of spatial dimensions is one. Here we use the term DNLS equation to denote the set of coupled ordinary differential equations resulting from discretizing *all* spatial variables in (1), while keeping the time-variable t continuous. However, one may also consider equations with discrete time (“fully discrete NLS equations”), as well as equations with only some of the spatial dimensions discretized (“discrete-continuum NLS equations”). The former are of interest as algorithms for numerical solution of (1), while the latter may describe pulse propagation in *arrays* of coupled nonlinear optical fibers (Aceves et al., 1995).

The simplest example of a DNLS equation can be formally obtained by just replacing the Laplacian operator in (1) with the corresponding discrete Laplacian. Thus, for the one-dimensional (1-d) case, we let $\phi_n(t) \equiv \phi(x = na; t)$ where a is the lattice parameter, so that for the particular case of cubic nonlinearity, the following equation is obtained:

$$i \frac{d\phi_n}{dt} + C(\phi_{n+1} - 2\phi_n + \phi_{n-1}) + \gamma|\phi_n|^2 \phi_n = 0, \quad (2)$$

where $C = 1/a^2$. This set of differential-difference equations with purely diagonal (“on-site”) nonlinearity is sometimes called the diagonal DNLS (DDNLS) equation, but since it is by far the most studied example of a DNLS equation, it is most commonly referred to

as simply *the* DNLS equation. Extensions to higher dimensions are straightforward, so that, for example, for a 2-d lattice with $x = ma$, $y = na$, the DNLS equation reads

$$i \frac{d\phi_{m,n}}{dt} + C(\phi_{m+1,n} + \phi_{m-1,n} + \phi_{m,n+1} + \phi_{m,n-1} - 4\phi_{m,n}) + \gamma|\phi_{m,n}|^2 \phi_{m,n} = 0. \quad (3)$$

The study of DDNLS equations has a long and fascinating history, beginning in the 1950s within solid-state physics with Holstein’s model for polaron motion in molecular crystals (Holstein, 1959); reappearing in the 1970s within biophysics with Davydov’s model for energy transport in biomolecules (see, e.g., Scott, 1999, Chapter 5.6), in the 1980s within physical chemistry in the theory of local modes of small molecules (see, e.g., Scott, 1999, Chapter 5.4), and within nonlinear optics modeling coupled nonlinear waveguides (see, e.g., Hennig & Tsironis, 1999, Chapter 1.4); and most recently around the turn of the century within matter wave physics in the description of a dilute Bose–Einstein condensate trapped in a periodic potential (Trombettoni & Smerzi, 2001). A brief account of experimental verifications of the validity of the DNLS description in the two latter contexts available at the time of writing was given in Eilbeck & Johansson (2003, Chapter 10). In addition, the DDNLS equation has played a central role in the development of the general theory for intrinsic localized modes (“discrete breathers”) in systems of coupled anharmonic oscillators during the 1990s (Flach & Willis, 1998). The reader should also note that the DDNLS equation is a particular example of the more general “discrete self-trapping” (DST) systems (described under a separate entry), where the general DST dispersion matrix describing interactions between lattice sites is restricted to nearest-neighbor couplings. Thus, the general theory described for DST systems is also applicable for the DDNLS equation.

The reason for the ubiquity of the DDNLS equation in nonlinear lattice systems is analogous to that of the NLS equation for continuum systems: it takes into account dispersion (through the nearest-neighbor interaction terms) as well as nonlinearity (the term $\gamma|\phi_n|^2 \phi_n$) at the lowest order of approximation. It can be derived, for example, from a general system of coupled anharmonic oscillators using a “rotating wave approximation” (RWA), where it is assumed that each oscillator approximately can be described by a complex rotating-wave amplitude as $u_n(t) = \text{Re}(\phi_n e^{-i\omega t})$ (see, e.g., Flach & Willis, 1998, Chapter 2.3; Scott, 1999, Chapter 5.3.1). Thus, the RWA assumes time-periodic solutions to have a purely harmonic time dependence, neglecting the generation of all higher harmonics. This approximation can be justified for small-amplitude oscillations in weakly coupled oscillator chains, using

perturbational techniques with expansions on multiple time scales (see, e.g., Flach & Willis, 1998, Chapter 2.2, for a general outline, and Morgante et al., 2002, Chapter 2.2, for details).

As for general DST systems, the DDNLS equation has, in addition to the energy (Hamiltonian) $H = \sum_n (C|\phi_{n+1} - \phi_n|^2 - \frac{\gamma}{2}|\phi_n|^4)$ (where ϕ_n and ϕ_n^* are canonical conjugated variables), a second conserved quantity, which is the excitation number $N = \sum_n |\phi_n|^2$. The conservation of excitation number results (through Noether's theorem) from the invariance of the equation under infinitesimal transformations of the overall phase ($\phi_n \rightarrow \phi_n e^{i\epsilon}$). As a consequence, the DDNLS equation is integrable for two degrees of freedom but nonintegrable for larger systems. Still, the existence of a second conserved quantity has some notable consequences, which makes the DDNLS equation nongeneric among general Hamiltonian lattice systems, such as:

- It has purely harmonic time-periodic solutions $\phi_n(t) = A_n e^{-i\omega t}$ with time-independent A_n ("stationary solutions").
- It has continuous families of time-quasi-periodic solutions, with two incommensurate frequencies, which may be spatially exponentially localized also in infinite systems ("quasi-periodic breathers") (see, e.g., Eilbeck & Johansson, 2003, Chapter 7; Kevrekidis et al., 2001, Chapter 2.4).

From a mathematical point of view, it is highly interesting that there also exist discretizations of the integrable 1-d cubic NLS equation that conserve its integrability. The most famous integrable DNLS equation is the so-called Ablowitz–Ladik (AL) DNLS equation, the integrability of which was first proven by Ablowitz & Ladik (1976). It is obtained by replacing the nonlinear term $\gamma|\phi|^2\phi$ with an "off-diagonal" discretization $\frac{\gamma}{2}|\phi_n|^2(\phi_{n+1} + \phi_{n-1})$, yielding

$$i \frac{d\phi_n}{dt} + C(\phi_{n+1} - 2\phi_n + \phi_{n-1}) + \frac{\gamma}{2}|\phi_n|^2(\phi_{n+1} + \phi_{n-1}) = 0. \quad (4)$$

Due to its integrability, it is possible to obtain exact analytical solutions to (4) describing, for example, traveling waves (in terms of elliptic functions, see, e.g., Scott, 1999, Chapter 5.3.2), solitons, and multisolitons. In particular, for $\gamma/C > 0$, there is a (bright) one-soliton solution given by (with rescalings such that $C = 1, \gamma = 2$):

$$\phi_n(t) = \sinh \beta \operatorname{sech}[\beta(n - vt)] e^{i(kn + \omega t + \alpha)}, \quad (5)$$

where β, k , and α are free parameters,

$$v = (2/\beta) \sinh \beta \sin k,$$

and $\omega = 2(\cosh \beta \cos k - 1)$. On the other hand, when $\gamma/C < 0$, there are dark-soliton solutions with

nonvanishing amplitude as $|n| \rightarrow \infty$ (Vekslerchik & Konotop, 1992).

The ALDNLS equation (4) also has a Hamiltonian structure with

$$H = \sum_n \left[-C\phi_n^*(\phi_{n+1} + \phi_{n-1}) + \frac{4C^2}{\gamma} \log \left(1 + \frac{\gamma}{2C} |\phi_n|^2 \right) \right],$$

although the conjugated variables ϕ_n and ϕ_n^* are noncanonical and the corresponding Poisson bracket deformed (see, e.g., Faddeev & Takhtajan, 1987, p. 303; Scott, 1999, Chapter 5.3.2). There is, at this writing, no known direct physical application of the ALDNLS equation; however, it is commonly used as a starting point for perturbational studies of physically more relevant equations such as (2). A particularly interesting model allowing interpolations between Equations (2) and (4) is the so-called "Salerno equation," which is described under a separate entry.

As a final example, we mention a rather complicated DNLS equation, which was introduced and proven to be integrable by Izergin and Korepin in 1981. This Izergin–Korepin equation reads

$$i \frac{d\phi_n}{dt} = 4\phi_n + \frac{P_{n,n+1}}{Q_{n,n+1}} + \frac{P_{n,n-1}}{Q_{n,n-1}}, \quad (6)$$

where

$$\begin{aligned} P_{n,n\pm 1} &= -\phi_n - \phi_{n\pm 1} \sqrt{\left(1 - \frac{\gamma}{8}|\phi_n|^2\right) \left(1 - \frac{\gamma}{8}|\phi_{n\pm 1}|^2\right)} \\ &+ \frac{\gamma}{4} \phi_n |\phi_{n\pm 1}|^2 + \frac{\gamma}{16} (|\phi_n|^2 \phi_{n\pm 1} + \phi_n^* \phi_{n\pm 1}^2) \\ &\times \sqrt{\frac{1 - \frac{\gamma}{8}|\phi_{n\pm 1}|^2}{1 - \frac{\gamma}{8}|\phi_n|^2}} \end{aligned}$$

and

$$\begin{aligned} Q_{n,n\pm 1} &= 1 - \frac{\gamma}{8} (|\phi_n|^2 + |\phi_{n\pm 1}|^2) \\ &- \frac{\gamma}{8} (\phi_n \phi_{n\pm 1}^* + \phi_n^* \phi_{n\pm 1}) \\ &\times \sqrt{\left(1 - \frac{\gamma}{8}|\phi_n|^2\right) \left(1 - \frac{\gamma}{8}|\phi_{n\pm 1}|^2\right)} \\ &+ \frac{\gamma^2}{32} |\phi_n|^2 |\phi_{n\pm 1}|^2. \end{aligned}$$

It is associated with a lattice Heisenberg magnet model, and turns into the cubic NLS equation in the continuum limit (see Faddeev & Takhtajan, 1987, pp. 299, for details).

DISCRETE SELF-TRAPPING SYSTEM

In the early 1980s, experimental evidence suggested that vibrational energy in natural proteins (specifically the CO stretch oscillation of the peptide unit) might become self-localized, with implications for the storage and transport of energy in biological organisms (Careri et al., 1984). Because the structures of natural proteins take a wide variety of shapes, the following equation—called the discrete self-trapping (DST) equation (Eilbeck et al., 1985)—was proposed to capture the essential features of self-localization:

$$\left(i \frac{d}{dt} - \omega_0\right) U + \gamma D(|U|^2)U + \varepsilon MU = 0. \quad (1)$$

Here, $U(t) \equiv \text{col}(u_1, u_2, \dots, u_f)$ is a column vector representing the amplitudes of f oscillatory modes, each of which is described in the rotating wave approximation by the complex amplitudes: $u_1(t), u_2(t), \dots, u_f(t)$. With $\gamma = 0$ and $\varepsilon = 0$, these modes (sites) oscillate independently and sinusoidally at the site frequency ω_0 .

In the last term of Equation (1), $M = [m_{jk}]$ is an $f \times f$ dispersion matrix, expressing energetic

interactions among the f modes stemming from electromagnetic couplings. This matrix is real and symmetric ($m_{ij} = m_{ji}$), and its diagonal elements can be chosen to represent small variations in the site frequencies from ω_0 . Thus, with $\gamma = 0$ but with the dispersion parameter ε not zero, there will be f modes of oscillation given by eigenvectors of the matrix $(M - \omega_0 I)$.

In the second term of Equation (1), the parameter γ introduces nonlinearity into the formulation, where $D(|U|^2) \equiv \text{diag}(|u_1|^2, |u_2|^2, \dots, |u_f|^2)$ is a diagonal matrix. Thus, with $\varepsilon = 0$ but with the nonlinear parameter γ not equal to zero, each site is an independent (uncoupled) anharmonic oscillator.

From a physical perspective, there are two types of nonlinearity: intrinsic (stemming from weakening of electronic bonding with mode amplitude) and extrinsic (arising from interactions between localized vibrations and the lattice) (Scott, 2003). Intrinsic nonlinearity governs energy localization in small molecules (such as “local modes” of the CH stretch oscillations in benzene), which has been known to physical chemists since the 1920s (Ellis, 1929).

With both γ and ε not equal to zero, the DST equation displays an interesting variety of regular and chaotic motions for various values of the energy

$$H = \sum_j \left(\omega_0 |u_j|^2 - \frac{\gamma}{2} |u_j|^4 \right) - \varepsilon \sum_{j,k} m_{jk} u_j^* u_k \quad (2)$$

and the “mass” $N = |u_1|^2 + |u_2|^2 + \dots + |u_f|^2$. Numerical studies of these motions provide insights into the dynamics of vibrational energy in proteins and in small molecules. (For descriptions at small levels of oscillatory energy, Equation (1) is conveniently quantized, Scott et al., 1994.)

The scaling $U \rightarrow U \exp(-i\omega_0 t)$ reduces (1) to the standard form of the DST equation

$$i \frac{d}{dt} U + \gamma D(|U|^2)U + \varepsilon MU = 0. \quad (3)$$

An important class of solutions of the DST equation are the so-called stationary solutions (“stationary” because amplitudes are time-independent), which satisfy the ansatz

$$U(t) = \mathbf{y} \exp(i\omega t).$$

Inserting this into (3), we see that the constant vector $\mathbf{y} = \text{col}(y_1, y_2, \dots, y_f)$ satisfies the nonlinear eigenvalue problem

$$-\omega \mathbf{y} + \gamma D(|\mathbf{y}|^2) \mathbf{y} + \varepsilon M \mathbf{y} = 0, \quad (4)$$

where ω plays the role of the eigenvalue. In many cases, the vector $\mathbf{y}$ can be chosen to be real. In the limit $\varepsilon \rightarrow 0$ (alternatively $\gamma \rightarrow \infty$), called the “anti-integrable” limit, we have $y_i = 0$ or $|y_i|^2 = \omega/\gamma$, and in the real case, we have $y_i = \pm \sqrt{N/K}$, where K is the

number of nonzero y_i on the chain. Starting from these solutions, branches of solutions for nonzero ε can then be generated numerically by path-following methods (Eilbeck et al., 1984). In the limit $\gamma \rightarrow 0$, (4) becomes a linear eigenvalue problem.

The values of y_i in the anti-integrable limit serve as a useful classification scheme for the branch, where we denote the three different (real) limits by the symbols $\cdot$, $\uparrow$, and $\downarrow$, respectively. The simplest stationary localized solution has only one nonzero mode or site amplitude in the anti-integrable limit, with $y_k = \sqrt{N}$, $y_i = 0$, $i \neq k$. For small but nonzero ε the amplitudes on the sites $\neq k$ are small and tend to zero exponentially as $|k - i| \rightarrow \infty$.

Such a localized solution was called a soliton in the early work on the DST equation but is now more often referred to as a breather due to its internal degree of freedom ω . A single breather in the center of a 1-dimensional lattice would be written as $(\dots \uparrow \dots)$, and would appear as in Figure 1. More complicated breather structures are possible, such as $(\dots \uparrow \uparrow \dots)$ and $(\dots \uparrow \downarrow \dots)$.

Breathers satisfying (4) are referred to as stationary breathers; more general mobile solutions are of interest. Feddersen (1991b) carried out a numerical study of solutions of the form

$$U_n(t) = \psi(n - ct)e^{i(kn - \omega t)}$$

in the case where M is a tridiagonal matrix with constant coefficients (nearest-neighbor interactions). This case is now known as the discrete nonlinear Schrödinger (DNLS) equation. Note that the “carrier wave” speed ω/k is different from the “envelope” speed c . He found branches of localized solutions to high accuracy, but the existence of such solutions is still an open question.

The stability criteria for stationary solutions of the DST equation were studied by Carr & Eilbeck (1985). An important step is to consider perturbations in a frame rotating with the stationary solutions

$$U_n(t) = [y_n + \varepsilon_n(t)]e^{i\omega t}.$$

Once this trick is carried out, the study of linear stability reduces to an algebraic eigenvalue problem, at least when f is finite, which greatly simplifies the problem. One noteworthy point is that the resulting stability matrix is not self-adjoint, so branches can change stability at points away from bifurcation points.

On a finite lattice, modeling vibrational modes on small molecules, the stationary solutions of the DST equation can often be found exactly. For $f = 3$ and $M_{ij} = 1$ if $i \neq j$ (modeling NH_3 stretching oscillations in ammonia), we obtain the bifurcation diagram shown in Figure 2. Details are discussed in Eilbeck et al. (1985). Note the change of stability of the $\uparrow \downarrow 0$ branch at two places, and the local-mode branch, where the

Figure 1. Stationary Breather on a DST (DNLS) lattice.

Figure 2. Stationary solutions on a DST lattice with $f = 3$. Solid (dotted) lines indicate stable (unstable) solutions.

vibrational energy is localized on a single degree of freedom.

In the large f case, in an application of the DST formulation to the dynamics of a globular protein, Feddersen considered interactions among CO stretch oscillations in adenylate kinase, which comprises 194 amino acids ($f = 194$) (Feddersen, 1991a). Since the structure of this enzyme has been determined by X-ray analysis, the $f(f - 1)/2 = 18721$ off-diagonal elements of the dispersion matrix (M) were calculated from Maxwell's equations. Also, diagonal elements were selected from a random distribution, and the degree of localization of a particular solution was defined by evaluating the quotient $\sum |u_j|^4 / \sum |u_j|^2$.

In this study at experimentally reasonable levels of nonlinearity (γ), stable localized solutions were observed near some but not all of the amino acids. Interestingly, this anharmonic localization was observed to be distinctly different from Anderson localization, a property of randomly interacting linear systems. Thus, none of the stationary states, that were observed to be highly localized at large γ , remained so as γ was made small. Also, none of the states, that were localized at $\gamma = 0$ (i.e., Anderson localized), remained so as γ was increased to a physically reasonable level.

Other studies and applications of the DST equation include models for Bose-Einstein condensates and coupled optical fiber arrays. On the theoretical side, work has been carried out in the study of nonstationary and chaotic solutions on both small and large lattices. A list of citations to Eilbeck et al. (1985) is presently maintained at <http://www.ma.hw.ac.uk/~chris/dst/>.

DISLOCATIONS IN CRYSTALS

Dislocations in crystals are linear topological defects near which the regular crystalline atomic arrangement is broken. The dislocation as a structural defect is characterized by the following peculiarity: the regular crystal lattice structure is greatly distorted only in the near vicinity of an isolated line (the dislocation axis), and the region of irregular atomic arrangement has transverse dimensions of the order of the interatomic distance. Nevertheless, deformation occurs even far from the dislocation core, and this is a consequence of a topological property of the dislocation. The deformation at a distance from the dislocation axis may be seen by passing along a closed contour around the dislocation core and considering the displacement vector of each crystalline site from its position in an ideal lattice. Upon calculating the total increment of this displacement vector at the end of the pass, one sees that the total atomic displacement is nonzero and equals one atomic translation period.

Among the many microscopic models of dislocations, the simplest takes the dislocation to be the edge of an extra half-plane present in the crystal lattice. In the conventional atomic scheme of this model (Figure 1), the trace of the half-plane coincides with the upper semiaxis y , and its edge coincides with the z -axis; thus, one has an “edge” dislocation. If one surrounds

Figure 1. Schematic atomic arrangement in the vicinity of an edge dislocation.

the dislocation axis with a tube with radius of the order of several interatomic distances, the crystal outside this tube may be regarded as ideal and subject only to elastic deformation (crystal planes are connected to one another almost regularly), and inside the tube the atoms are considerably displaced relative to their equilibrium positions and form the “dislocation core.” The atoms of the dislocation core are distributed over the contour of the shaded pentagon in Figure 1. The closed pass is the external contour starting from point 1 and finishing at point 2. The vector connecting atoms 1 and 2 is denoted by b and called the “Burgers vector.” Possible values of the Burgers vectors in a crystal are determined by its crystallographic structure and correspond, as a rule, to a small number of certain directions in a crystal. The dislocation lines are arranged arbitrarily, although their arrangement is limited by a set of definite crystallographic planes. The dislocation line cannot end inside a crystal. It must either leave the crystal with each end on the crystal surface or form a dislocation loop.

The main topological property of the dislocation implies that a dislocation in a crystal is a specific line D having the following general property. After a circuit around the closed contour L enclosing the line D (see Figure 2), the elastic displacement vector u changes by a certain finite increment b equal to one of the lattice periods. This property can be written as

$$\oint_L du_i = \oint_L \frac{\partial u_i}{\partial x_k} dx_k = -b_i, \quad (1)$$

assuming that the direction of the circuit is related to a chosen direction of the tangent vector τ to the dislocation line. The dislocation line is in this case a line of singular points of the elastic fields.

Macroscopic considerations (based on elasticity theory) allow one to find a concentration of strains and stresses near the dislocation. The elastic field created by a dislocation leads to its interaction with

Figure 2. Mutual coordination of the vector τ and circuit around the contour L .

Figure 3. Edge dislocation in the Frenkel-Kontorova model.

other dislocations and other types of crystal defects. In particular, the dislocation can accumulate point defects near its core. If such defects are color centers, the dislocation line can be decorated (See **Color centers**).

Displacements of the dislocation line in the plane determined by the vectors $\mathbf{b}$ and $\boldsymbol{\tau}$ (called a "slip plane") have no effect on the crystal continuity. Therefore, a comparatively easy mechanical motion of the dislocation is possible in principle in this plane. But any displacement of the dislocation produces some plastic deformation, so moving dislocations are carriers of crystal plasticity.

Macroscopic dislocation theory can describe a contribution of the dislocations to mechanical properties of real crystals and proposes a physical explanation of the crystal plasticity. However, the macroscopic theory cannot propose a structure of the dislocation core and explain possible mechanisms of the dislocation motion. The Soviet scientists Yakob Frenkel and Tatiana Kontorova were the first to present a simple 1-dimensional microscopic dislocation model (Frenkel & Kontorova, 1938). To formulate their model, it is convenient to analyze the following picture. The atomic chain (a set of black circles in Figure 3) is an edge series of one half of a plane crystal ($y > 0$, Figure 1) displaced in a certain way with respect to another half of a crystal (a substrate at $y < 0$). The influence of the nondisplaced half of the crystal on the atoms distributed along the x -axis can be qualitatively described assuming that those atoms are in a given external periodic field whose period coincides with the interatomic distance on the substrate a . The chain energy is then determined not only by a relative displacement of neighboring atoms but also by an absolute displacement of separate atoms u_n (n is the atomic number) in the external field. If

the external periodical field has a simple sine-shaped dependence, the equation of chain motion has the form

$$m \frac{d^2 u_n}{dt^2} = \alpha (u_{n+1} + u_{n-1} - 2u_n) - U_0 \sin(2\pi u_n/a), \quad (2)$$

where m is the atom mass and α and U_0 are constant parameters. The displacements of the atoms in the chain are performed in such a way that $N+1$ atoms are situated over N crystal sites on the substrate. This atom distribution corresponds to the following boundary conditions for the displacements:

$$u_n = a \quad \text{at} \quad n = -\infty, \quad u_n = 0 \quad \text{at} \quad n = \infty. \quad (3)$$

Equation (2) and the boundary conditions (3) are basic in the Frenkel-Kontorova model.

In a long-wavelength approximation, the function of the discrete number u_n is replaced by a continuous function of the coordinate $u(x)$ where $x = na$, and Equation (2) transforms into the sine-Gordon equation (SG) equation

$$\frac{\partial^2 w}{\partial t^2} = s^2 \frac{\partial^2 w}{\partial x^2} - \omega_0^2 \sin w, \quad w = 2\pi u/a, \quad (4)$$

where $s^2 = a^2 \alpha / m$ and $\omega_0^2 = U_0 / m$.

The SG equation (4) possesses the following (kink-soliton) solution satisfying the boundary conditions (3): $u(x) = \tan^{-1} \exp[-(x - x_0)/l]$, where $l = s/\omega_0$ and $x_0 = \text{constant}$. This kink describes the distribution of atoms in the core of the Frenkel-Kontorova dislocation, the parameter l determines the dislocation semiwidth, and x_0 is the coordinate of the dislocation center. Later Peierls (1940) proposed a semimicroscopic model of a straight dislocation line (directed along the z -axis in Figure 1) in a 3-d isotropic elastic medium. In this model, it was assumed that strains around the dislocation are described by the theory of elasticity; however, the interaction energy of both semi-spaces above (+) and under (−) the slide plane depends periodically on the relative displacements $v(x) = w(x)^+ - w(x)^-$ (the x -axis is a trace of the slide plane) and is described by a sine-shaped periodic function of $v(x)$. The main equation of Peierls's theory has the following form:

$$a \int_{-\infty}^{\infty} \left(\frac{dv}{dx} \right) \frac{d\xi}{x - \xi} + M \sin v = 0, \quad (5)$$

where the integral means its principal value and M is some dimensionless combination of elastic modules. Equation (5) has a soliton solution very close to the Frenkel-Kontorova dislocation $w(x) = \pi + 2 \tan^{-1}[(x - x_0)/l]$ where $l = \pi a / M$.

Figure 4. Two types of dislocation motion in the Peierls potential field. (a) Dislocation oscillates in its own trough. (b) The dislocation forms a kink moving along the z -axis.

Both the chain energy in the 1-d case and crystal energy in the 3-d case (calculated for the Frenkel–Kontorova and Peierls models, respectively) do not depend on the coordinate of the dislocation center x_0 . Thus, the dislocation can glide, changing its location on the slide plane without action of any external field. This fact is a result of using the continuous approximation. Taking into account discreteness of the crystal and following the Peierls theory, Nabarro (1947) showed that a moving dislocation is influenced by some crystal field periodically depending on the dislocation center x_0 (later called the “Peierls relief”). Therefore, the dislocation can start moving only if an external stress acting on it exceeds a certain value called the “Peierls barrier.”

Many dynamic problems in dislocation theory can be analyzed using the so-called “string model.” This model treats the dislocation line as a heavy string under tension lying on a corrugated surface. An effective mass per unit length of the dislocation m and its line tension T_D are of a field origin and are associated with the inertia and energy of dislocation dynamic elastic field (Kosevich, 1964). The corrugated surface describes the Peierls relief. Troughs of this surface correspond to the potential minima of the slide plane occupied by a straight-line dislocation in equilibrium (see Figure 4). If the z -axis is directed along the equilibrium position of the dislocation and its transverse displacements η go along the x -axis, then the equation of motion of the dislocation has the form (Seeger, 1956):

$$m \frac{\partial^2 \eta}{\partial t^2} - T_D \frac{\partial^2 \eta}{\partial x^2} + b \sigma_p \sin(2\pi \eta/a) = b \sigma, \quad (6)$$

where σ_p is the Peierls stress and σ is the applied stress. In the case $\sigma = 0$, this equation is equivalent to Equation (4), proposed by Frenkel and Kontorova. Equation (6) describes both small amplitude vibrations of the dislocation effected by an external oscillation force and the so-called kink-mechanism of the transverse displacements of the dislocation along the x -axis effected by a strong stationary driving force.

DISPERSION MANAGEMENT

The propagation of optical pulses in fiber lines is usually limited by dispersion and nonlinearity. Dispersion causes a broadening of the pulses whereas nonlinearity is the reason for four-wave mixing (FWM). A balance of dispersion and nonlinearity may produce the so-called optical soliton. Dispersion management (manipulations of the chromatic dispersion along the line) is an attractive technique that allows enhancement of the performance of fiber communication links both for soliton and nonsoliton transmission. Dispersion-managed solitons can be viewed as novel kinds of information carriers with many attractive features that will lead to further improvement of the transmission capacity of fiber links. The starting point of all considerations in this area is the cubic nonlinear Schrödinger (NLS) equation for an optical mode in a cylindrical fiber with (constant) dispersion and Kerr nonlinearity (Newell & Maloney, 1992):

$$i \frac{\partial u}{\partial z} + \frac{1}{2} \frac{\partial^2 u}{\partial t^2} + |u|^2 u = 0. \quad (1)$$

This equation is written in dimensionless form (u is the normalized intensity, z the normalized propagation distance, and t is the normalized time); for more details, see, for example, Hasegawa & Kodama (1995).

From FWM calculations (Agrawal, 1995), one knows that the FWM efficiency depends on the phase mismatch and thereby on the dispersion coefficient, D . The larger the phase mismatch (proportional to dispersion), the smaller the efficiency of FWM. On the other hand, small D values are necessary for high bit-rates B . One reason is the so-called Gordon–Haus effect (Gordon & Haus, 1986). Solitons adjust themselves to external perturbations, and thereby they can be considered as quite robust. However, this adjustment also has disadvantages. Any re-shaping, for example, in the presence of amplifier noise, also has consequences

Figure 1. Schematic plot of the dispersion coefficient that varies in space when dispersion management is applied.

for the velocities. Changing velocities cause a timing jitter, and the latter limits the maximal possible bit-rate. Note that the general soliton solution of Equation (1)

$$u_s = A \operatorname{sech}[A(t + \Omega z) - q_0] e^{-i\Omega t - (i/2)(A^2 - \Omega^2)z + i\phi_0} \quad (2)$$

is moving with velocity $v = -1/\Omega$. The detailed calculation (Gordon & Haus, 1986) gives an upper limit for the bit-rate B and the length L of the system in the form

$$(BL)^3 \leq \text{upper limit} \sim \frac{1}{D}. \quad (3)$$

One clearly recognizes that low dispersion favors high bit-rates over large distances. On the other hand, as was mentioned already, low dispersion is dangerous with respect to FWM. Dispersion management is an elegant way out of this dilemma.

Principle of Dispersion Management

The idea of using a dispersion-compensating fiber (DCF) to overcome the dispersion of the standard mono-mode fiber (SMF) was proposed in 1980 (Lin et al., 1980). The simplest optical-pulse equalizing system consists of a transmission fiber (SMF) or dispersion-shifted fiber (DSF) and an equalizer fiber with the opposite dispersion (DCF to compensate SMF or, for instance, SMF to compensate DSF with normal dispersion). The incorporation of a fiber with normal dispersion reduces (or, in the ideal case, eliminates) the total dispersion of the fiber span between two amplifiers. Low average dispersion is good for reducing the Gordon–Haus effect while high local dispersion reduces the FWM efficiency. In Figure 1, we indicate the principle of dispersion management by a schematic drawing.

Dispersion management means that the coefficient in front of the second time derivative becomes Z -dependent (we change notation in order to allow for different normalization parameters), that is, the simplest form of the dispersion-managed nonlinear Schrödinger equation becomes (Kodama, 1998)

$$i \frac{\partial q}{\partial Z} + \frac{1}{2} d(Z) \frac{\partial^2 q}{\partial T^2} + |q|^2 q = 0. \quad (4)$$

A short remark: if $d(Z)$ would be $\neq 0$ everywhere in the fiber, the variation of $d(Z)$ can be eliminated by using a new coordinate Z' via

$$\frac{dZ'}{dZ} = d(Z). \quad (5)$$

Then a Z -dependent coefficient would appear in front of the nonlinear term. Again, we would end up with an equation with a rapidly varying coefficient. However, characteristic for nearly all practical dispersion management arrangements is the vanishing of $d(z)$ at certain positions z .

Weak Dispersion Management

For weak dispersion management of small-amplitude pulses, one can start with the equation

$$i \frac{\partial u}{\partial z} + d(z) \frac{\partial^2 u}{\partial t^2} + \varepsilon |u|^2 u = 0. \quad (6)$$

Here,

$$\begin{aligned} d(z) &= \langle d \rangle + \tilde{d} \quad \text{for } 0 \leq z \leq l, \\ d(z) &= \langle d \rangle - \tilde{d} \quad \text{for } l \leq z \leq 2l, \end{aligned} \quad (7)$$

and so on, is the z -dependent dispersion. The z -coordinate is made dimensionless with the dispersion length of the local dispersion, that is, $\tilde{d} \sim O(1)$. The averaged dispersion $\langle d \rangle$ is assumed to be small, and we introduce the smallness parameter $\varepsilon \ll 1$ via $\langle d \rangle \approx \varepsilon$. Nonlinearity will also be scaled by ε . The strength of the dispersion management is characterized by

$$R(z) = \int_0^z (d - \langle d \rangle) ds. \quad (8)$$

Weak dispersion management means $R \sim O(\varepsilon^{1/2})$; that is, R is assumed to be small. From the definition $R \sim O(\tilde{d} \cdot l)$ holds. Therefore, the length l (of the parts with constant dispersion) is also small compared with the dispersion length, $l \sim O(\varepsilon^{1/2})$.

One can use (at least three different) averaging methods to calculate the average behavior of pulses over large distances. The first one is a direct method, starting with an expansion. The second one uses the Lie-transform technique; it is, therefore, much more systematic than the direct method. The third method makes use of a Bogolyubov transformation, which is very elegant in practice, but the ansatz is not as straightforward as the Lie transformation. The ansatz has to be specifically chosen for each problem. In the direct method (Kivshar & Spatschek, 1995; Yang et al., 1997), one expands u in orders of $\varepsilon^{1/2}$ and applies a multiple scale technique,

$$\begin{aligned} u &= U + u_1 + u_2 + \dots, \\ \frac{\partial}{\partial z} &= \frac{\partial}{\partial \xi} + \frac{\partial}{\partial z_0} + \frac{\partial}{\partial z_1} + \dots \end{aligned} \quad (9)$$

with $U = U(z_0, z_1, z_2, \dots)$ and $u_k = u_k(\xi, U)$. One may use the scaling $\xi \sim O(\varepsilon^{-1/2})$, $z_k \sim O(\varepsilon^{k/2})$, $u_k \sim O(\varepsilon^{k/2})$, where $\langle u \rangle = U$, $\langle u_k \rangle = 0$.

The Lie transformation technique was originally developed for ordinary differential equations but can also be used for a partial differential equation (Neyfeh, 1973). To apply the Lie transformation one rearranges Equation (6) into the form

$$\begin{aligned} \frac{\partial u}{\partial z} &= i \langle d \rangle u_{tt} + i\varepsilon |u|^2 u + i\tilde{d} u_{tt} \\ &= X_0 + \tilde{d} X_{0D} = X[u, u^*]. \end{aligned} \quad (10)$$

X depends on the infinite set of variables $(u, u_t, u_{tt}, \dots, u^*, u_t^*, u_{tt}^*, \dots)$, indicated by $X[u, u^*]$. Obviously $X_0 \sim O(\varepsilon)$, $X_{0D} \sim O(1)$. The transformation

$$\begin{aligned} u &= e^{\tilde{\phi} \nabla} v = v + \phi + \frac{1}{2!} (\tilde{\phi} \cdot \nabla) \phi \\ &\quad + \frac{1}{3!} ((\tilde{\phi} \cdot \nabla) \phi \cdot \nabla) \phi + \dots \end{aligned} \quad (11)$$

transforms Equation (10) into

$$\frac{\partial v}{\partial z} = Y[v, v^*]. \quad (12)$$

The right-hand side can, in principle, be derived appropriately in order to identify v with the averaged intensity. Here, $\tilde{\phi} = (\phi, \phi_t, \dots)$ and $\nabla = (\frac{\partial}{\partial v}, \frac{\partial}{\partial v_t}, \dots)$ are infinite-dimensional vectors.

In the third method (Arnol'd, 1988), one uses a Floquet–Lyapunov transformation

$$u(z, t) = e^{iR(z)\partial_z^2} B(z, t) \quad (13)$$

as well as the Bogolyubov–Krylov transformation

$$\begin{aligned} B &= v + i f |v|^2 v + (g + p) N_1(v) \\ &\quad + i h N_2(v) + q |v|^4 v + O(\varepsilon^{5/2}), \end{aligned} \quad (14)$$

with coefficients to be determined appropriately during the calculation. All three methods lead to the same result. Over fairly large distances, the averaged solution is still a fundamental soliton, that is, robust. This follows from the fact that *to lowest order*, the basic equation for the averaged pulse intensity is the *integrable* cubic nonlinear Schrödinger equation

$$iv_z + \langle d \rangle v_{tt} + \varepsilon |v|^2 v = \frac{1}{2} \varepsilon \langle R^2 \rangle N_2(v). \quad (15)$$

The correction term on the right-hand side contains a polynomial N_2 in v , v_t , v_{tt} , $\dots$. One should bear in mind, on the other hand, that on the short scale (length $2l$ of one of the periodic elements), the exact (non-averaged) solution is oscillating (breathing) with the frequency following from the periodicity in the dispersion map. Besides the scaling $\tilde{d} \sim O(1)$ and $R \sim O(\varepsilon^{1/2})$, other scalings are possible and tractable

Figure 2. Plot of a DM soliton. The lower part shows the breathing over one element of the dispersion map. The upper graph shows the fine structure on a logarithmic axis, indicating the characteristic deviations from the fundamental soliton.

by the methods mentioned above, as long as R is small (weak dispersion management).

Strongly Dispersion-Managed Solitons

Recently (Nijhof et al., 1998), the strong dispersion management (R is no longer small) became of increasing interest. The chirp (pulse phase has a quadratic time-dependence) is a new and one of the most important features of the (strongly dispersion managed) DM soliton (recall that the conventional soliton is unchirped). In addition, the DM soliton is not anymore of the sech-type. The DM soliton consists of a self-similar energy-containing core surrounded by oscillating tails. Such tails manifest themselves as non-self-similar modulations of the soliton profile during the compensation period, although their amplitudes are rather small compared with the main peak (see Figure 2).

The most surprising feature of the DM soliton is that it can propagate stably along the line with zero or even with normal average dispersion (in contrast to the fundamental soliton that propagates stably only in the anomalous dispersion region). These observations indicate that an average model describing the evolution of the breathing pulse differs from the nonlinear Schrödinger equation. In other words, strong dispersion management imposes such a strong perturbation that a carrier pulse in this case is no longer the NLS soliton. For more details, see Nijhof et al. (1998).

Experimental Results

One can estimate the potential of dispersion management from successful experiments, for example, Carter et al. (1999).

DISPERSION RELATIONS

Dispersion relations (DRs) are associated with wave equations to characterize the nature of their temporal and spatial evolution. For a linear wave equation in one dimension, the DR expresses the wavenumber ($k = 2\pi/\lambda$) as a function of the frequency ($\omega = 2\pi/T$), or vice-versa, where λ and T are, respectively, the wavelength and temporal period of an elementary periodic solution. Through the superposition principle, the behaviors of all solutions of linear equations are determined by the DR. In nonlinear cases, DRs also depend on wave amplitude and can be used in perturbative analyses of quasiharmonic systems. For more than one spatial dimension, the wave number is a vector.

Dispersion Relations for Linear Equations

Fourier analysis establishes a one-to-one correspondence between DRs and equations in such a way that we

can obtain one from the other. Consider as an example, the Klein–Gordon equation,

$$u_{tt} - u_{xx} + m^2 u = 0, \quad (1)$$

where m is a constant and the subscripts indicate partial derivatives. Substituting a plane-wave solution of the form $u(t, x) = ae^{i(\omega t - kx)}$ into (1), we obtain the DR

$$\omega^2 = m^2 + k^2. \quad (2)$$

For linear equations, the phase velocity $v_\phi(k)$ and the group velocity $v_g(k)$ are defined as

$$v_\phi(k) = \frac{\omega(k)}{k}, \quad v_g(k) = \frac{d\omega(k)}{dk}. \quad (3)$$

The phase velocity of a wave number k is the speed of propagation of the corresponding harmonic wave component or mode. The group velocity corresponds to the propagation speed of a wave packet, and thus is the speed of energy transmission for the system (Whitham, 1974). This distinction is especially important in the propagation of wave trains, where signals travel with the group velocity.

An equation (or the wave that is represented by its solution) is said to be *dispersive* if $v_\phi(k)$ is not a constant (or equivalently if $v_\phi \neq v_g$ for all k). In such cases, the initial profile of the wave is not conserved. For the Klein–Gordon equation we have

$$v_\phi(k) = \pm \frac{\sqrt{m^2 + k^2}}{k}, \quad v_g(k) = \pm \frac{k}{\sqrt{m^2 + k^2}}, \quad (4)$$

and the equation is dispersive except in the special case $m = 0$ (which corresponds to the wave equation).

The DR also plays an important role in simulations of Equation (1) by finite differences. The usual (von Neumann) stability conditions are equivalent to requiring that the phase velocity in the mesh be greater or equal to the phase velocity of the equation (Ritchmyer & Morton, 1967). Other aspects that mark deviations of numerical solutions from continuous solutions are governed by discrete DRs (Trefethen, 1982).

Amplitude-Dependent Dispersion Relations

For nonlinear equations, solutions cannot, in general, be expressed as a superposition of plane waves and thus, in principle, there is not dispersion relation. There are nevertheless two possible applications of the concept. The first is in the small-amplitude regime where an approximate DR can be established by neglecting the higher order terms, and the second is when plane waves are particular solutions of the nonlinear equation. In both cases, the DRs are amplitude dependent. We illustrate both cases with a nonlinear Klein–Gordon equation and the cubic Schrödinger equation.

The nonlinear Klein–Gordon equation with cubic term

$$u_{tt} - u_{xx} + m^2 u + g u^3 = 0 \quad (5)$$

does not have exact plane wave solutions. (The case $m = 1$, $g = -1/3!$ corresponds for instance to the first two terms expansion of the sine-Gordon equation.) Nevertheless, we may assume a term of the form $a \cos(\omega t - kx)$ in the solution. Substituting and retaining only the lower-order terms, we obtain the approximate DR

$$-\omega^2 + k^2 + m^2 + \frac{3}{4} g a^2 + \dots = 0 \quad (6)$$

provided $m^2 \gg g a^2$. The presence of coupled higher-order terms together with the approximate DR gives a picture of how such modes get excited and evolve.

The previous analysis can also be applied, for instance, to the cubic nonlinear Schrödinger equation

$$i\phi_t - \phi_{xx} + |\phi|^2 \phi = 0, \quad (7)$$

but this equation is special in the sense that it has particular solutions in the form of plane waves $\phi = a e^{i(\omega t - kx)}$. Although the general solution cannot be expressed as a superposition of such plane waves, we have an amplitude-dependent DR of the form

$$\omega = k^2 + a^2. \quad (8)$$

In this case, wave dispersion can be compensated by nonlinearity and solitons may appear.

DISTRIBUTED OSCILLATORS

Two modes of oscillation sharing a common source of energy may have a stationary solution of equal mode amplitudes, but this solution may be unstable for the following reason. One of the modes will inevitably gain a bit of amplitude (due to noise), and if it then consumes more than its share of the available power, it will grow further, changing the other mode to decrease. Interestingly, this effect depends upon the spatial dimension of the oscillating system. Related dynamics arise in diverse areas of engineering and science, including flip-flop circuits, multimode lasers, interacting biological species, and the neocortex of a human brain.

Figure 1. A unit cell of a two-dimensional oscillator array.

As a model for mode interactions, consider a two-dimensional array of identical oscillators, each interacting only with its nearest neighbors. Power flow among the modes of such an array can be studied using the method of harmonic balance, introduced by Balthasar van der Pol in 1934 (van der Pol, 1934) and developed by applied mathematicians and engineers in the Soviet Union during the 1930s and 1940s (Andronov et al., 1966; Kryloff & Bogoliuboff, 1947).

As shown in Figure 1, a unit cell of the array consists of a nonlinear conductance $I(v)$ in parallel with a capacitance C , connecting a lattice point to a ground plane. Each lattice point is attached to its four nearest neighbors through an inductance L . The nonlinear conductance is represented as

$$I(v) = -Gv(1 - 4v^2/3V_0^2), \quad (1)$$

so for $-V_0/2 < v < V_0/2$ the differential conductance (dI/dv) is negative.

Assume a large, square $(N \times N)$ lattice of these unit cells with zero-voltage (short circuit) boundary conditions on the edges, as in Figure 2. In a zero-order approximation, the nonlinear conductance can be neglected, and in a continuum approximation, this linear, lossless system supports an arbitrary number (say n) modes. Thus, the total voltage is

$$v(x, y, t) = V_1(x, y) \cos \theta_1 + V_2(x, y) \times \cos \theta_2 + \dots + V_n(x, y) \cos \theta_n, \quad (2)$$

which depends on space (x and y) and time (t) where

$$V_i(x, y) \equiv V_i \cos k_{xi} x \cos k_{yi} y \quad \text{and} \quad \theta_i \equiv \omega_i t + \phi_i.$$

Noting that the energy in the i th mode is related to its amplitude by $U_i = (N^2 C/8) V_i^2$ and averaging the

Figure 2. A 4×4 array ($N^2 = 16$) of the unit cells in Figure 1.

product of current (given by Equation (1)) and voltage (given by Equation (2)) over space and time gives the rate of change in mode energies as functions of mode energies (Scott, 2003).

The rate of change of energy (or power) into the first mode is

$$\frac{dU_1}{d\tau} = U_1 \left[1 - \alpha \left(\frac{9}{8} U_1 + U_2 + \cdots + U_n \right) \right], \quad (3)$$

with $\tau \equiv Gt/C$ and $\alpha \equiv 4/(N^2 CV_0^2)$. For n excited modes, there is a set of n equations—each similar to Equation (3) but with the indices appropriately altered—for the rates of change of the mode energies as functions of those energies. These nonlinear, autonomous equations have the same form as those introduced by Vito Volterra to describe the interaction of biological species competing for the same food supply (Volterra, 1937), and they are similar to a formulation suggested by Peter Greene (Greene, 1962) to describe interactions between assemblies of neurons in the brain.

Generalizing to a system of d -space dimensions, equations of interacting mode energies become

$$\begin{aligned} \frac{dU_1}{d\tau} &= U_1 [1 - \alpha (KU_1 + U_2 + \cdots + U_n)], \\ &\vdots \\ \frac{dU_n}{d\tau} &= U_n [1 - \alpha (U_1 + U_2 + \cdots + KU_n)], \end{aligned} \quad (4)$$

where

$$K = 3^d / 2^{d+1}.$$

For $K > 1$ (implying $d \geq 2$), analysis of Equations (4) indicates multimode stability. In other words, several modes can stably exist for two or more spatial dimensions. For one spatial dimension, on the other hand, two modes of equal amplitude are unstable, and only a single mode can be stably established. This observation is important in the design of semiconductor lasers, where large transverse dimensions are introduced to increase the power output.

Figure 3. A Necker cube.

Unfortunately, such a design allows several modes to oscillate together, thereby decreasing the coherence and spectral purity of the output beam.

Multimode oscillator arrays have been realized using semiconductor tunnel diodes (Scott, 1971), superconductor tunnel diodes (Hoel, et al., 1972), and integrated circuits (Aumann, 1974). In these experiments, a variety of stable multimode oscillations have been observed, some quasiperiodic and others periodic, indicating mode locking. In a manner qualitatively similar to that proposed by Greene in his model of the brain's neocortex (Greene, 1962), the oscillator array can be induced to switch from one stable multi-mode configuration to another.

At the level of subjective perception, similar switchings in the brain are observed as one stares at Figure 3. Constructed by Louis Albert Necker (a Swiss geologist) in the mid-1800s, this image seems to jump from one metastable orientation to another, like the flip-flop circuit of a computer engineer. Defining order parameters (ξ_1 and ξ_2) to represent neural activities corresponding to the two perceptions of the Necker cube, Hermann Haken has recently suggested the equations

$$\begin{aligned} \frac{d\xi_1}{d\tau} &= \xi_1 [1 - C\xi_1^2 - (B + C)\xi_2^2], \\ \frac{d\xi_2}{d\tau} &= \xi_2 [1 - C\xi_2^2 - (B + C)\xi_1^2] \end{aligned} \quad (5)$$

as an appropriate dynamic description (Haken, 1996). With $U_j = \xi_j^2$ ($j = 1, 2$), Equations (5) are identical to Equations (4), showing only single-mode stability for $B > 0$. Study of this system in the (ξ_1, ξ_2) phase plane reveals two stable states: $(1/\sqrt{C}, 0)$ and $(0, 1/\sqrt{C})$, and jumping back and forth between these two states models one's subjective experience of Figure 3.

DNA PREMELTING

DNA premelting phenomena are spontaneous dynamical processes that occur well below the melting temperature of DNA. They reflect DNA “breathing,” a process that combines the transient unstacking of base-pairs (allowing planar drugs and dyes to intercalate into DNA), with the transient breaking and rejoining of hydrogen-bonds connecting base-pairs in limited DNA regions (allowing tritium nuclei in hydrogen bonds connecting base-pairs to exchange with protons in water). The formation and propagation of chain-slippage structures either within or between homologous DNA molecules, along with a variety of structural phase transitions in DNA are also included in discussions of premelting. This entry describes how concepts of kink-antikink-bound states (breather solitons) have been used to assist in understanding a wide range of DNA premelting phenomena.

Conceptually, the lowest energy kink-antikink-bound state in DNA (termed a “premelton”) contains a central hyperflexible beta-DNA core region modulated into B-DNA on either side through kink and antikink boundaries. As the kink and antikink move together, for example, the energy density in the central beta-DNA core region rises. This energy is used first to enhance (alternate) base-pair unstacking, and next, to stretch and to eventually break hydrogen-bonds connecting base-pairs. As kink and antikink move apart, the reverse occurs. Energy within this central core region falls, allowing hydrogen-bonds to reform, and (alternate)

base-pairs to partially restack. Isoenergetic breather-motions such as these can facilitate the intercalation of drugs and dyes into DNA and allow tritium exchange to occur at temperatures well below the melting temperature.

Beta-DNA is a structural form that differs from either B- or A-DNA. Evidence for its existence comes from studies of intercalation by drugs and dyes into DNA and the binding of certain proteins to DNA. Although double-stranded, beta-DNA is unique in being both hyperflexible and metastable. Its hyperflexibility suggests it be a liquid-like phase, lying intermediate between the more rigid B- and A-forms and the melted single-stranded form. Both properties necessitate beta-DNA to be pinned by an intercalator or held by a protein in order to be studied in detail. The structure is composed of repeating units called beta-structural elements. These are a family of base-paired, dinucleotide structures, each possessing the same mixed sugar-puckering pattern (i.e., C3' endo (3'–5') C2' endo) and having similar backbone conformational angles, but varying in the degree of base-unstacking. Lower energy forms contain base-pairs that are partially unstacked, while higher energy forms contain base-pairs completely unstacked.

Beta-DNA is an intermediate in DNA melting, lying on the minimal energy pathway connecting B-DNA with single-stranded melted DNA. Three distinctly different sources of nonlinearity appear as DNA chains unwind, and these determine the sequence of conformational changes that occur along this pathway.

The first two sources of nonlinearity stem from changes in the sugar-pucker conformations and base-pair stacking. These changes require small energies (ca. kT) and appear as part of the initial structural distortions accompanying DNA unwinding. Starting with B-DNA, the effect of unwinding DNA is to counterbalance this with an equal but opposite right-handed superhelical writhing to keep the linking invariant. This is achieved through a modulated beta-alternation in sugar-puckering along the chains, accompanied by the gradual partial unstacking of alternate base-pairs. The lowest energy beta-DNA structure emerges as an end result. Its metastability reflects the presence of additional energies in its structure that cause the partial unstacking of alternate base-pairs.

The third source of nonlinearity arises from the stretching and ultimate rupture of hydrogen bonds connecting base-pairs. At first, beta-DNA accommodates further unwinding through the gradual loss of superhelical writhing. This reflects the appearance of beta-structural elements having increasingly higher energy (these have base-pairs further unstacked and unwound). Eventually, however, a limit is reached and further unwinding begins to stretch hydrogen-bonds that connect the base-pairs. Continued unwinding results in the disruption of these hydrogen-bonds, and the appearance

Figure 1. Molecular structure of a B-B premelton.

Figure 2. Molecular structure of a B-A premelton.

of single-stranded DNA. This final sequence of conformational change defines the boundary that connects beta-DNA to single-stranded melted DNA.

Using nonlinear least-squares methods, it has been possible to form premelton structures within B-DNA and within A-DNA (i.e., B-B premeltons, and A-A premeltons), as well as hybrid structures that connect the two (i.e., B-A premeltons and A-B premeltons) (see Figures 1 and 2). Such hybrid premeltons are constructed by connecting the central beta-DNA core with either type of kink-antikink boundary. Importantly, B-B and A-A premeltons are nontopological, whereas B-A and A-B premeltons are topological.

The B to A structural phase transition can be understood in the following way. In the presence of suitable thermodynamic conditions, kink and antikink within premeltons in B-DNA structure begin to move apart to form larger and larger core regions, whose centers modulate into A-DNA structure. Eventually, B-A premeltons and A-B premeltons form, and these continue to move apart, leaving a growing A-DNA region within. Such a mechanism is reversible and illustrates how a bifurcation within the central core region of this low-energy kink-antikink bound state structure can give rise to the B- to A-DNA structural phase transition.

Bifurcations arising within premeltons having higher energy (containing longer beta-DNA core regions that undergo more vigorous breather-motions) can lead to the formation of two additional types of higher energy kink-antikink bound states in DNA. These are called "branch-migratons" and "dislocatons." Each gives rise to different types of chain-slippage events, called double- and single-strand branch-migration.

Branch-migratons arise from breathing events that cause DNA chains to come apart transiently, and to then snap back, at nucleotide base sequences having 2-fold symmetry. Weakly hydrogen-bonded hairpin-

like structures initially form. These are lengthened by a series of kinetic steps in which hydrogen-bonds connecting base-pairs within dinucleotide elements in vertical stems are broken and simultaneously reformed in horizontal stems (or vice versa) in a concerted 2-fold symmetric process. This phenomenon is called "cruciform-extrusion." A branch-migraton contains four stems; each stem contains kink (or antikink) boundaries connecting beta-DNA core regions with surrounding B-DNA.

Dislocatons arise at repetitive base sequences, for example, in poly-d(G-A): poly-d(C-T). Again, these structures form as a result of particularly energetic breathing events that cause DNA chains to come apart, and to then "snap back," forming small single-stranded bubble-like protrusions on opposite chains. These protrusions can then move apart, leaving growing regions of beta-DNA in between. The centers of these regions modulate into kink and antikink boundaries, and these, in turn, continue to move apart leaving B-DNA. The net result is the appearance of pairs of dislocatons, each moving in opposite directions along DNA. Movement involves single-chain slippage and is remarkably similar to the mechanism underlying moving crystal lattice dislocations, hence, the term dislocaton.

The formation of these two different kinds of higher energy kink-antikink bound state structures is another example of bifurcations emanating within the centers of premeltons. The underlying source of nonlinearity that determines the path of the bifurcation is the breaking and reforming (after chain-slippage) of hydrogen bonds connecting dinucleotide base-pairs. The decision as to whether branch-migratons or dislocaton pairs form is determined by information coded in the nucleotide base-sequence. This information constitutes the bias.

The combined presence of torsional and writhing strain energies found in negatively superhelical circular

DNA increases the probability that branch-migratons and dislocatons form at the appropriate sequences. These energies are first used to form premeltons. They are next used to form dislocatons or branch-migratons, and to propagate chain-slippage events.

Although B- and A-DNA are right-handed double-helical structures, DNA molecules containing the alternating poly-d(G-C): poly-d(G-C) sequence can, under certain conditions, assume a left-handed double-helical conformation (i.e., in the presence of high salt and/or negative superhelicity). This structure, called Z-DNA, contains the dinucleotide (G-C) as the asymmetric unit, held together by base-pairs. Being a left-handed double-helical structure, Z-DNA contains sugar-phosphate backbone conformations radically different from either B- or A-DNA.

The B to Z transition is proposed to occur as a result of a bifurcation that takes place during the formation of the dislocaton. As before, DNA breathing within the premelton takes place, followed by chains snapping back to form pairs of single-stranded, bubble-like protrusions on opposite chains. As pairs of protrusions move apart, Z-DNA forms within. The molecular boundaries that allow the helix to "swing left," capitalize on the additional flexibility and length provided by the single-stranded DNA regions on opposite DNA chains. B to Z boundaries form simultaneously on both ends in a concerted two-fold symmetric process. This is a direct consequence of the nonlinearity that ties the process together. A prediction of the model is the appearance of single-stranded DNA regions juxtaposed to beta-DNA regions within each B-Z junction, which is supported by experimental evidence.

DNA SOLITONS

In the early 1970s, Alexander Davydov and his colleagues began studies of nonlinear conformational waves in α -helix proteins. Englander et al. (1980) extended these ideas to DNA, interpreting open states (also called bubbles or local unwound regions, evidenced in hydrogen exchange experiments) as solitary waves, which can be viewed as kink solutions of the sine-Gordon (SG) equation. To understand the relation between the SG equation and DNA, we begin with models of the structure and dynamics of DNA.

Tightly packed in the nuclei of living cells, DNA consists of two polynucleotide chains (Figure 1). The chemical structure of each chain consists of periodically repeating phosphate groups and sugar rings (shown by dark ribbons), and irregular nitrous bases (shown in gray). Sequences of four types of bases (adenine, thymine, guanine, and cytosine) occur in DNA, forming the genetic code. These two polynucleotide chains interact weakly through hydrogen bonds and wind around each other to produce the double helix.

The internal structure of DNA is rather flexible. Thermal collisions with molecules of the surrounding solution, action of radiation, and local interactions with proteins, drugs, or other ligands induce several types of internal motions. Among these are

- small-amplitude oscillations of individual atoms;
- rotational, transverse, and longitudinal displacements of the atomic groups (phosphate groups, sugars, and bases);
- motions of the double chain fragments, having several base pairs lengths;

Figure 1. DNA molecule packing into the cell nucleus (courtesy of Nicolas Bouvier).

Figure 2. Hierarchy of models of DNA structure and dynamics.

- local unwinding of the double helix; and
- transitions of DNA fragments from one conformational form to another (e.g., from A- to B-form).

Thus, the DNA molecule is a complex dynamical system with many types of internal motions having different energies, velocities, amplitudes, frequencies, and lifetimes (McCammon & Harvey, 1987).

To describe the motions of DNA, different approximate models may be used, as indicated in Figure 2. The simplest model resembles a fragment of elastic thread (or rod), which ignores the internal structure. This model emerges naturally from microphotos where the DNA molecule does indeed resemble a thin elastic thread. Under this formulation only three coupled differential equations are needed: one for longitudinal displacements, another for angular displacements, and a third for transverse displacements. In Figure 2 a discrete analog of the model is placed nearby in the same row.

In the second row of Figure 2, a more complex model recognizes that DNA consists of two polynucleotide chains while ignoring the internal structure. Thus, the model has two weakly interacting elastic threads that wind around each other in a double helix. A mathematical formulation of this model requires six coupled differential equations—three for each of the two helices. The discrete version of the model and two simplified versions where the helical structure is neglected are shown nearby.

In the third row a more complex model is presented, taking into account that each of the polynucleotide chains comprises three types of atomic groups (phosphate groups, sugar rings, and nitrous bases) and representing solid-like motions of each of the atomic groups. Under this model, the required number of equations dramatically increases.

The model shown in the fourth row takes into account the internal motions of the atomic groups while

neglecting variations of the base pairs (genetic code). Finally, the most accurate model is shown in the fifth line, which represents positions and motions of all atoms of the DNA molecule. The number of differential equations required to describe the motions in both of these models is inconveniently large at present levels of computer development.

To see the relation between DNA and the SG equation, apply the first model of the second row to study the opening of base pairs. The mathematical formulation of this model comprises six coupled differential equations that are nonlinear because base pair opening is a motion of large amplitude. Following Englander et al. (1980) we assume that rotational motions of bases around the sugar-phosphate chains make the greatest contribution to the process of opening, reducing the number of equations to two. Considering the rotational motions of bases in only one of the chains (accounting for the other chain as some averaged external field) reduces the number of equations from two to one.

To obtain the form of this single equation, an analogy between rotational motions of DNA bases and rotational motions of pendula in a mechanical model of the SG equation is convenient (See **Laboratory models of nonlinear waves**). Thus, the pendula of the mechanical model can be considered as analogs of DNA bases, the horizontal spring as an analog of one of the two sugar-phosphate chains, and the gravitational field as an averaged field formed by the second chain interacting with the first chain through hydrogen bonds. The analogy between these two dynamical systems suggests that the equation describing rotational motions bases in DNA should be an SG equation, with parameters defined as follows:

- I is the moment of inertia of bases.
- K is the coefficient of rigidity of the sugar-phosphate chain.
- V_0 is a potential function that represents interactions of bases through hydrogen bonds.
- R_0 is the radius of DNA.
- a is the distance between bases along the chains.

The variable of the equation is Ψ (the angle of rotations of bases around one of the two sugar-phosphate chains), and the equation itself is

$$I \frac{\partial^2 \Psi}{\partial t^2} - K R_0^2 a^2 \frac{\partial^2 \Psi}{\partial z^2} + V_0 \sin \Psi = 0, \quad (1)$$

where z indicates distance along the molecule. Kink solutions of this equation describe the opening of base pairs.

Another type of DNA soliton has been obtained by Peyrard & Bishop (1989), who studied melting and denaturation of DNA. Supposing that transverse (rather than rotational) motions of bases make the most contribution to the process, they reduced the number of equations from six to two, and after a simple linear

transformation, they obtained two independent equations describing transverse displacements in phase and out of phase. The first of the equations was nonlinear and its solitary wave solutions were interpreted as bubbles appearing in the DNA structure as temperature was increased.

Solitary wave solutions obtained by Englander et al. (1980) and by Peyrard and Bishop (1989) were improved later by investigators who considered other types of internal motions and their interactions, effects of dissipation and inhomogeneity, and interactions with surroundings. These refinements led to additional solitary wave solutions that have been used to interpret experimental data on hydrogen-tritium exchange, resonant microwave absorption, and neutron scattering by DNA. Such studies help us to understand transitions between different DNA forms, long-range effects, regulation of transcription, DNA denaturation, protein synthesis (e.g., insulin production), and carcinogenesis (Scott, 1985; Gaeta et al., 1994; Yakushevich, 1998).

DOMAIN WALLS

In ferromagnetic materials, small regions of correlated magnetic moments formed below the critical temperature are called domains. Domain walls are two-dimensional structures that separate distinct do-

main of order and form spontaneously when a discrete symmetry (such as time-reversal symmetry in magnets) is broken at a phase transition. With each subdivision of a substance into distinct domains, there is a decrease in the bulk energy because the order parameter value inside each domain minimizes its free energy. However, there is a simultaneous increase in the energy of interaction between differently aligned domains giving rise to an extra surface energy at the boundaries between neighboring domains. Consequently, this competition leads to an average domain size that gives the lowest overall free energy in a material sample, which is quantified below.

The energy of a ferromagnetic domain wall is calculated as arising from the exchange interactions between spins augmented by the anisotropy energy, while the exchange energy for N spins of magnitude S comprising a domain wall varies as

$$E_{\text{exch}} = \frac{\pi^2 J S^2}{N}, \quad (1)$$

where J is the exchange constant and the anisotropy energy is

$$E_{\text{anis}} = K N a^3, \quad (2)$$

where a is the lattice constant and K the anisotropy constant. Minimizing the sum with respect to N yields

$$N = \sqrt{\frac{\pi^2 J S^2}{K a^3}} \quad (3)$$

giving the domain width as $\Delta = Na$.

A Bloch domain wall is a region separating two (magnetic) domains within which magnetization changes gradually by rotating in the plane perpendicular to the line along the direction from one domain to the next. This way the magnetization direction experiences a reversal by 180° without changing its magnitude. The energy associated with a domain wall decreases with the width of the wall, and domain wall thickness is found as a minimization problem involving the anisotropy energy. A Neel domain wall, on the other hand, involves magnetization reversal in the plane perpendicular to the boundary between two domains.

Domains undergo reorganization under the effects of applied fields and can move in space. This occurs especially in the initial phase of remagnetization favoring those domains that are aligned with it and thus setting their boundary in motion to occupy more space, and it is followed by reorientation of the magnetization within each domain that is not aligned with the field.

Domain walls also exist in other systems, including crystals, ferroelectrics, metals, alloys, liquid crystals, and so on. In annealing metals, for example, domain walls appear as the grain boundaries between two sharply different compositions. Generically, the underlying physical quantity is called the order

parameter and is specific for a given substance. (For the annealing metal it is a real field, while in superfluid helium it is a complex-valued field.) Over most of the sample, the order parameter has a constant magnitude, but the sign (when it is real) or the phase (when complex) is not fixed and can change from place to place. A real order parameter field may be positive in one region of space and negative in its neighborhood, the continuity of the field implies that it must cross the zero value on a surface between them. This transition region is a domain wall.

In all types of critical systems, domain walls arise due to the competition between the bulk part of the free energy, which in the Landau theory of phase transitions is a quartic polynomial in the order parameter ϕ , and the surface energy term, which is due to inhomogeneities and varies as the square of the order parameter gradient following Ginzburg. Minimizing this type of free energy functional

$$F = \int \left[A_2 \phi^2 + A_4 \phi^4 + D \left(\frac{d\phi}{dx} \right)^2 \right] dx \tag{4}$$

leads to a stationary nonlinear Klein–Gordon (NLKG) equation for the order parameter as a function of the spatial variable

$$D\phi'' = A\phi + B\phi^3, \tag{5}$$

where $A = A_2$ and $B = 2A_4$. One of its stable solutions is proportional to $\phi_0 \tanh(x/\xi)$ where $\xi = \sqrt{-8D/A}$, which describes a smooth function that interpolates between the two homogeneous phases $\phi = \pm \sqrt{-A/B}$. For magnetization as an order parameter, this solution represents a magnetic domain wall (in one space dimension), and for ferroelectrics, where the order parameter is a polarization vector, this represents a ferroelectric domain wall. For crystals undergoing structural phase transitions, there can also be a kinetic energy term in the free energy functional leading to a standard form of the NLKG equation

$$-m\ddot{\phi} + D\phi'' = A\phi + B\phi^3. \tag{6}$$

This solution is a moving domain wall (or kink)

$$\phi = \phi_0 \tanh[(x - vt)/\xi] \tag{7}$$

as shown in Figure 1 (Krumhansl & Schrieffer, 1975).

Nonlinear traveling solitary waves have also been investigated in ferroelectrics where kinks representing domain walls were shown to carry an electric dipole flip (Benedek et al., 1987). Domain walls in ferroelectrics are typically several unit cells wide, while in ferromagnets their thickness is several hundred or even thousands of unit cells. This difference is due to the exchange interactions between spins that are much stronger than the dipole-dipole interactions in ferroelectric crystals.

Figure 1. A typical form of a domain wall (or kink).

Geometry	Defect
Sheet-like	domain walls, membranes
Line-like	vortices, strings
Point-like	monopoles, hedgehogs

Table 1. Geometry of space and the corresponding topological defects.

There also exist cylindrical domains in magnets. As can be seen from Table 1, domain walls are examples of topological defects, and as such, they are very common in all broken-symmetry phenomena that take place slowly enough to allow for the generation of defects. Modern particle physics predicts that phase transitions occurred in the early universe following the Big Bang. Of particular interest to cosmology is the production of topological defects, which may be sheet-like, line-like, or point-like concentrations of energy.

DOPPLER SHIFT

The Doppler shift (or Doppler effect) is named after the Austrian scientist Christian Doppler, who in 1842 noticed that the observed frequency of waves from a source depends on how it is moving relative to the observer. In its simplest form, applicable to motions that are slow compared with the wave speed, it is quite easy

to visualize and understand. If a source of waves at some frequency f is approaching an observer, the frequency f' that the observer detects is higher than would be the case were the two at rest with respect to each other. From the point of the observer, he is "running into" the waves, while from the point of view of the source, the waves are being "bunched up." The opposite effect occurs when a source is moving away from an observer, and the general situation can be expressed as

$$\frac{f'}{f} = 1 + (v/c) \cos \theta, \quad (1)$$

where v is the relative speed, c the speed of the waves, and θ the angle between the wave propagation and the relative velocity. The $\cos \theta$ factor is simply a statement that the only important component of the relative velocity which can contribute to the shift is that along the direction of wave propagation. As long as v is small compared with the speed of light, this expression works well for most applications, and is quite appropriate to discuss the frequency shift of reflected radar signals used to detect speeding motorists (where c would be the speed of light) or the rise and fall in the pitch of a train whistle or an ambulance siren as it approaches and passes (in which case c would be the speed of sound).

One of the most famous experiments ever done to demonstrate the Doppler shift was done by the Dutch meteorologist Buys-Ballot who put a group of musicians on a train and then had them hold a constant note while racing past him as he stood on the platform.

The Doppler shift often appears more than once in a single application. For example, in police radar, electrons in the metal of an approaching car see a higher frequency radar signal than the police officer emits. They then re-emit radio waves at a higher frequency that is in turn seen at a still higher frequency by the officer being approached.

When speeds involved are very large, the effects of special relativity come into play. While it is possible to outrun a sound wave, the speed of light is the same no matter how the source moves. If we take c to be the speed of light and consider the Doppler shift for light (or any other electromagnetic wave), we have

$$\frac{f'}{f} = \frac{1 + (v/c) \cos \theta}{\sqrt{1 - v^2/c^2}}. \quad (2)$$

A good discussion of special relativity including the Doppler shift is that of Rindler (1991), and a particularly elegant geometric derivation of the formula under very general conditions can be found in Burke (1980). The additional term in the denominator of Equation (2) is due to time dilation whereby a moving clock appears to go more slowly than one at rest. In this case there is a Doppler shift even when $\cos \theta = 0$, which is referred to as the "transverse Doppler effect." One might imagine that it would be very difficult to detect, but in the special case where the sources are in random thermal

motion, the leading $(v/c) \cos \theta$ term averages to zero and merely broadens spectral lines of atoms without actually shifting them. This "thermal Doppler effect" due to the transverse Doppler effect was measured by Pound and Rebka in 1960 using the Mössbauer effect. Interestingly, the nontransverse Doppler shift itself played an important role in that measurement.

The Doppler effect has numerous practical applications. In addition to its use already mentioned in measuring automobile velocities, these include Doppler radar for studying weather based on measuring the speeds of raindrops blown by wind (see, e.g., Doviak & Zmric, 1993) and imaging moving tissues such as the heart in echocardiography, or measuring the speed of blood flow through an artery (see, e.g., Evans & McDicken, 2000).

The Doppler effect is also a valuable tool for pure science and has played a key role in many experiments upon which our present view of the world is based. Edwin Hubble used it to determine the velocities of distant objects in space from shifts in their spectral lines (shifted toward the red end of the spectrum, hence redshift), finding that distant objects seem to be moving away from us with speeds that increase with their distance (Christianson, 1995). This discovery is the basis of modern cosmology and is one of the strongest pieces of evidence that the universe had its origins in a Big Bang. The Doppler shift has also been used in delicate and beautiful experiments that demonstrate the time dilation effects of gravity. Both these gravitational effects on time and the relativistic effect in the transverse Doppler shift must be taken into account in order for the Global Positioning System (GPS) to function properly.

DOUBLE-WELL POTENTIAL

See **Equilibrium**

DRESSING METHOD

The dressing method is a technique of constructing and solving nonlinear partial differential equations of

integrable models. It is based on dressing transformations that are symmetries of nonlinear partial differential equations and act on the Lax operators as gauge transformations on the connection (Zakharov & Shabat, 1974). Accordingly, the form of the linear spectral problem and the zero-curvature conditions are preserved.

The basic concept of the dressing method (Zakharov & Shabat, 1974) is that starting from known solutions of the underlying linear problem, one obtains new solutions of the transformed ("dressed") linear problem. Suppose Ψ_0 is a solution of the following linear problems:

$$\left(\frac{\partial}{\partial t_i} - E_i^{(0)} \right) \Psi_0(t_1, \dots, t_n, \lambda) = 0, \quad i = 1, \dots, n, \quad (1)$$

where $t_1, t_2, \dots, t_n$ are independent flow variables and $E_i^{(0)}$ are complex $m \times m$ mutually commuting matrices that depend on the spectral parameter λ . The matrix Ψ_0 is referred to as a "bare" wave function and commuting operators $L_i^{(0)} = \partial/\partial t_i - E_i^{(0)}$ as "bare" Lax operators.

For the soliton equations in $1+1$ (one spatial and one time) dimensions, the dressing transformations are generated by the dressing matrices $\Theta_{\pm}$ which can be defined by the Riemann–Hilbert factorization problem (Zakharov & Shabat, 1974; Faddeev & Takhtajan, 1987). Given a Lie group of functions $g(\lambda)$ on the contour $\mathcal{C}$ in the complex plane, one finds a new (dressed) wave function through the factorization problem:

$$\Psi_0(t_1, \dots, t_n, \lambda) g(\lambda) \Psi_0^{-1}(t_1, \dots, t_n, \lambda) = \Theta_-^{-1}(t_1, \dots, t_n, \lambda) \Theta_+(t_1, \dots, t_n, \lambda), \quad (2)$$

where $\Theta_-^{-1} = (\Psi_0 g \Psi_0^{-1})_-$ and $\Theta_+ = (\Psi_0 g \Psi_0^{-1})_+$ have analytic continuation inside or outside the contour $\mathcal{C}$, respectively. The dressing transformation defines a new wave function $\Psi^{(g)} = \Theta_- \Psi_0 g = \Theta_+ \Psi_0$, which is a solution of new linear problems:

$$\left(\frac{\partial}{\partial t_i} - E_i \right) \Psi^{(g)}(t_1, \dots, t_n, \lambda) = 0, \quad (3)$$

where

$$E_i = \frac{\partial \Theta_-}{\partial t_i} \Theta_-^{-1} + \Theta_- E_i^{(0)} \Theta_-^{-1} = \frac{\partial \Psi^{(g)}}{\partial t_i} (\Psi^{(g)})^{-1} \quad (4)$$

satisfy the compatibility conditions also known as zero-curvature conditions:

$$\frac{\partial E_j}{\partial t_i} - \frac{\partial E_i}{\partial t_j} - [E_i, E_j] = 0. \quad (5)$$

Comparing the expression for E_i from Equation (4) with $E_i^{(0)} = (\partial \Psi_0 / \partial t_i) \Psi_0^{-1}$, following from Equation (1), one sees that the dressing transformations preserve the form of the Lax connections $L_i = \partial/\partial t_i - E_i$. A

related approach also exists, which yields the dressing matrix in terms of the Fredholm type of integral operator entering the Gel'fand–Levitan–Marchenko equation (Zakharov & Shabat, 1974). Both dressing approaches are equivalent.

By considering two successive dressing transformations associated with two group elements g_1 and g_2 , one naturally arrives at the concept of the group of the dressing transformations with $\Psi^{(g_1 g_2)} = (\Psi^{(g_1)})^{(g_2)}$. The general theory of dressing transformations and its group was developed by Semenov–Tian–Shansky (1985), who also introduced a Poisson bracket covariant under the dressing group action on the phase space of functions E_i . With such a bracket, the group of the dressing transformations induces on a phase space a Lie–Poisson action and turns out to be a symmetry of the phase space. Furthermore, it was observed that the group of the dressing transformations appears as a semi-classical limit of the quantum group symmetry of the two-dimensional integrable quantum field theories. Hence the group of the dressing transformations appears to be a classical precursor of the quantum group structure of an integrable field system in two dimensions (Babelon & Bernard, 1992). In many integrable models, the N -soliton solutions can be thought of as elements of the dressing group orbit of the vacuum state. Accordingly, successive dressing transformations can be used to build N -soliton solutions from the vacuum solution. In Babelon & Bernard (1993), the authors presented the construction of N -soliton solutions by dressing transformations in the sine-Gordon model. The dressing group also admits an elegant interpretation within the Kyoto school (Date et al., 1983) approach to the integrable models appearing in this context as a transformation group of the τ -function.

For equations in $2+1$ (two spatial and one time), dimensions, one applies the dressing technique based on a nonlocal Riemann–Hilbert problem for Kadomtsev–Petviashvili I and Davy–Stewartson I equations as well as the N -wave equations. The nonlocal (D-bar) $\bar{\partial}$ problem is required for the Kadomtsev–Petviashvili II and Davey–Stewartson II equations (Zakharov & Manakov, 1985).

The nonlocal (D-bar) $\bar{\partial}$ -problem gives rise to the $\bar{\partial}$ -dressing method in which an $N \times N$ quasi-analytical matrix function of $\lambda, \bar{\lambda}$ $\chi(\lambda, \bar{\lambda}, x)$, $x \in \mathbb{C}^n$ satisfies the following nonlocal $\bar{\partial}$ -problem:

$$\frac{\partial \chi(\lambda, \bar{\lambda})}{\bar{\lambda}} = \hat{R} \chi = \int \int_C d\lambda' d\bar{\lambda}' \chi(\lambda', \bar{\lambda}') R(\lambda', \bar{\lambda}', \lambda, \bar{\lambda}), \quad (6)$$

with R being a kernel of a linear integral operator $\hat{R}$. The set of commuting differential operators defined in terms of commuting rational matrix functions I_i :

$$D_i \chi = \frac{\partial \chi}{\partial x_i} + \chi I_i(\lambda), \quad i = 1, \dots, n, \quad (7)$$

defines an integrable system. Let the integral linear operator $\hat{R}$ commute with all differential operators D_i , $[D_i, \hat{R}] = 0$. Then, the choice $I_1 = \lambda$, $I_2 = \lambda^2$, $I_3 = \lambda^3$ leads for $N = 1$ to the KP II equation: $(u_t + u_{xxx} + 6uu_x)_x + 3u_{yy} = 0$ with $u = 2\partial\chi_1/\partial x_1$ where χ_1 is the term in an asymptotic expansion ($\lambda \rightarrow \infty$) of $\chi = 1 + \chi_1/\lambda + \chi_2/\lambda^2 + \dots$

DRIPPING FAUCET

A dripping faucet may easily be seen in everyday life. Its rhythm is sometimes regular but sometimes not, which sensitively depends on the flow of water. If the rhythm is irregular, one might blame it on noise due to unseen influences such as small air vibrations. However, it is nowadays well known that the irregularity arises from deterministic chaos instead of stochastic noise. In fact, this system is a good example showing that chaos is not only a mathematical product but also a phenomenon ubiquitous in the real world.

Chaotic dripping was originally suggested by Otto Rössler (Rössler, 1977) and the first experimental study was performed by Robert Shaw and his colleagues (Shaw, 1984; Martien et al., 1985). They measured the time interval (T_n) between the n th drip and its successor, and obtained a time series $\{T_1, T_2, \dots\}$. To detect

Figure 1. (a) An experimental strange attractor reconstructed from the observation of the oscillation, deformation, and breakup of drops hanging from a nozzle (7 mm inner diameter and 10 mm outer diameter). The projection of the orbit onto the plane $(z, \dot{z})$ is presented, where z is the center of mass and $\dot{z}$ is its velocity. The flow rate $Q = 0.24$ g/s (~ 2 drips/s on average). Inset of (a): return map of the dripping time interval (T_n). (b) Fluid dynamic simulation for 7 mm nozzle diameter. $Q = 0.32$ g/s. Inset of (b): drop deformation.

possible determinism from a nonperiodic time series, they made a return map (plot of (T_n, T_{n+1}) for each n). A return map for nonperiodic dripping is shown in the inset of Figure 1(a). If irregular numbers $T_1, T_2, \dots$ were generated stochastically by throwing the dice, the plots would look like a set of random points with no particular structure. The observed map actually exhibited a clear structure, which implies a deterministic rule existing in the seemingly random outcomes.

As suggested by Rössler, the deterministic randomness, chaos is expected if two oscillating variables couple: (i) damped oscillation of the drop position (z , the center of mass) due to the surface tension of the water and (ii) relaxation oscillation of the mass of the drop (m) due to the filling-and-discharging process. A minimal model including these variables is the so-called mass-spring model described as

$$\frac{d}{dt} \left(m \frac{dz}{dt} \right) = -kz - \gamma \frac{dz}{dt} + mg, \quad (1)$$

where g is the acceleration of gravity, k is the spring constant, and γ is the damping parameter. The mass

increases at a constant flow rate Q as

$$\frac{dm}{dt} = Q. \quad (2)$$

The model assumes that when the position z reaches a critical point, a part of the total mass (Δm) breaks away. Shaw used this model to explain the dripping dynamics as low-dimensional chaos.

Since then, dripping faucets have attracted many physicists, and a wide range of nonlinear behavior has been reported, such as strange attractor, period-doubling bifurcation, Hopf bifurcation, intermittency, hysteresis, crisis, and satellite drop formation. On the other hand, theoretical studies mainly rested on the mass-spring model, and any direct link between this simple model and the physics of drop formation was not known. The basic dynamics inherent in the complex behavior of the dripping faucet system was revealed quite recently, owing to detailed analyses of (i) experiments for a wide range of flow rates (Katsuyama & Nagata, 1999), (ii) fluid dynamic simulations using a new algorithm (Fuchikami et al., 1999), and (iii) the improved mass-spring model based on the fluid dynamic simulations (Kiyono & Fuchikami, 1999).

The fluid dynamic simulations clearly visualized how drops are formed and pinched off repeatedly (see figures in color plate section):

- The water under the faucet, increasing at a constant flow rate, forms a drop, which bulges until m reaches $\sim m_{\text{crit}}$ (the maximum mass for the static stable state) and the surface tension is overwhelmed by the gravitational force.
- Then its sides begin to shrink, forming a rapidly narrowing neck (necking process) and the drop is soon pinched off (breakup). In the necking process, the drop undergoes almost free-fall.
- Because the water is stretched downward at the breakup moment, the surface tension works as a restoring force just after the breakup, which causes oscillation of the water. Thus the position z , the center of mass of the water, moves downward with up-and-down oscillation.
- After m reaches m_{crit} again, the necking followed by the breakup is repeated.
- The phase of oscillation at the onset of the necking process affects the breakup moment, the mass at that moment, and so the remnant mass ($m_r = m - \Delta m$).
- If the phase changes periodically, the motion is periodic (for example, in the period-two motion $T_1, T_2, T_1, T_2, \dots$, the phase changes as $\theta_1, \theta_2, \theta_1, \theta_2, \dots$), while the phase is random in chaotic motion.

The essential information obtained from the fluid dynamic simulations is as follows:

- (i) The state point of the water is well described in the limited phase space ($z, dz/dt, m$), even if the water,

Figure 2. A section of the bifurcation diagram of the improved mass-spring model obtained by decreasing the control parameter Q , the flow rate. Hysteresis is observed in certain ranges of Q (indicated with $\leftrightarrow$). Inset: a hysteresis curve.

an infinite-dimensional system, deforms its shape in a complex way. (Remember z denotes the center of mass.)

- (ii) The instability of the shape of water induces the instability of the chaotic orbit. In other words, stretching of the chaotic attractor mainly occurs in the beginning of the necking process.
- (iii) After the breakup, the renewed (i.e., remnant) mass realizes various values, while the renewed position and velocity are confined in a small region, well approximated as constants. Thus the attractor is compressed and becomes low dimensional.

These features have also been confirmed experimentally. Figure 1 presents a recent experiment (a) and the corresponding fluid dynamic simulation result (b). The low-dimensional (almost one-dimensional) pattern of the return map (inset of (a)) suggests that the system can be described by a low-dimensional dynamical system. The experimental trajectory in the phase space ($z, dz/dt, m$) was reconstructed from the continuous change of the drop shape observed. The spiral orbit indicates that the drop oscillates several times and then makes free-fall in the necking process before breakup. The drop shape obtained from the simulation (inset of (b)) is very close to the experimental result.

The observation of the drop formation process made it possible to improve the traditional mass-spring model by taking account of several points ignored so far, which include

- the mass dependence of the spring constant: $k = k(m)$;
- the necking process by setting $k = 0$ for $m > m_{\text{crit}}$; and
- the mass dependence of the remnant mass: $m_r = m_r(m)$, where m is the mass just before the breakup.

Bifurcation diagrams (plot of T_n versus Q) obtained from the improved mass-spring model reproduce the global structure of experimental bifurcation diagrams for a wide range of flow rates, Q . As seen in Figure 2,

one distinct feature is a repetition of similar “units.” The neighboring units are very similar but gradually become complex as Q is increased. Each unit is characterized by an integer that is the number of oscillations of each drop before breakup. This number decreases with increasing Q because the drop mass reaches the critical value sooner. In Figure 2, for example, there are three units and the corresponding numbers are 6, 5, 4 from left to right. Units in a range of relatively large Q include various types of bifurcations, such as period-doubling cascade to chaos, intermittency, and hysteresis (inset of Figure 2), while units in a range of sufficiently small Q include just period one motion. The bifurcation diagrams for small faucet diameters also exhibit a relatively simple structure.

The improved mass-spring model systematically explains the characteristic complexities of low-dimensional chaos (Ott, 1993) inherent in dripping dynamics. However, the model can be applied only when Q is small enough so that drops are clearly separated from each other. For larger flow rates, experimental results are so complex that approximations used in the fluid dynamic simulations do not work. New theoretical approaches are required, especially to interpret Hopf bifurcation and statistical features of satellite drops.

DRUDE MODEL

In 1900, Paul Drude developed his theory of metallic conduction of electricity, following the discovery of the electron by Joseph John Thomson in 1897. Applying the kinetic theory of gases to a metal,

considered as a gas of electrons, he made the following assumptions:

- (i) Each electron moves according to Newton’s law of motion in the presence of external fields until it collides with other electrons or ions. Between collisions, interactions with both the other electrons and with the ions are neglected.
- (ii) Collisions are instantaneous events that abruptly alter the velocity of an electron. The probability per unit time that an electron experiences a collision is given by $1/\tau$, where τ is called the collision time, mean free time, or relaxation time.
- (iii) Electrons are assumed to achieve thermal equilibrium with their surroundings only through collisions. After each collision, the electron emerges with a randomly directed velocity whose magnitude is given by the temperature.

Note that in contrast to a classical gas of neutral molecules, the electrons move against a background of positively charged immobile ions.

The Drude model considers an average electron representative for the whole ensemble. Newton’s equation of motion is

$$m \frac{d^2}{dt^2} \mathbf{r} + \frac{m}{\tau} \frac{d}{dt} \mathbf{r} = -e\mathbf{E}, \quad (1)$$

where $\mathbf{r}$ is the spatial drift coordinate (excluding the random thermal motion), m is the effective mass of the electron, $e > 0$ is the electron charge, and $\mathbf{E}$ is the applied electric field. The second term is a friction term arising from collisions. This equation can be rewritten in terms of the electron momentum $\mathbf{p} = m\mathbf{v} = m d\mathbf{r}/dt$, where $\mathbf{v}$ is the drift velocity,

$$\frac{d}{dt} \mathbf{p} + \frac{\mathbf{p}}{\tau} = -e\mathbf{E}. \quad (2)$$

In the overdamped case the momentum induced by the electric field is given by

$$\mathbf{p} = -e\tau\mathbf{E}. \quad (3)$$

The current density is obtained by multiplying the drift velocity of the mean electron by the electron charge and by the density per unit volume n of all electrons

$$\mathbf{j} = -en\mathbf{v} = en \frac{e}{m} \tau \mathbf{E} = en\mu\mathbf{E}, \quad (4)$$

where the drift mobility $\mu = (e/m)\tau$ has been introduced. This is Ohm’s law, with constant conductivity $\sigma = en\mu$.

The classical Drude model neglects electron-electron interactions, heating of the electrons, non-equilibrium dynamics, and quantum transport effects, and is thus restricted to low fields, moderate carrier densities and temperature ranges. If any of these

conditions are violated, nonlinear and non-Ohmic conduction arises. Such effects are abundant in metals and semiconductors and may lead to instabilities and bifurcations of self-sustained oscillations or self-organized spatiotemporal patterns (Shaw et al., 1992, Schöll, 2001).

In the simplest case, a local, instantaneous conductivity $\sigma = en\mu$ still exists, but n or μ depends upon the field E (generation-recombination or drift instability, respectively), leading to a nonlinear or even nonmonotonic current density-field relation $j = en(E)\mu(E)E$, possibly with a range of negative differential conductivity (NDC), where $dj/dE = en\mu + e(dn/dE)\mu(E)E + en(d\mu/dE)E < 0$.

In an extension of the simple Drude picture, those nonlinearities may be due to a dependence of the momentum relaxation time upon the field (drift instability) or upon the electron temperature that, in turn, depends upon E (electron overheating instability, as a result of changes in the dissipation of energy and momentum). They may also be due to dependence of the carrier density upon field (generation-recombination instability, as in avalanche breakdown). More complex situations arise if the (semi)conductor consists of several layers of different materials, and intrinsic inhomogeneities render the notion of a local conductivity inappropriate. In particular, this applies to low-dimensional nanoscale structures (Ferry & Goodnick, 1997) or mesoscopic conductors (Datta, 1995), where the characteristic length scales may be such that the device dimension becomes smaller than the mean free path, the quantum mechanical phase relaxation length, and the de Broglie wavelength of the electron. Then various nonlinear transport regimes occur, where ballistic or non-equilibrium or coherent quantum effects dominate.

DUFFING EQUATION

Serious studies of forced nonlinear oscillators appeared early in the 20th century when Georg Duffing (1918) examined mechanical systems with nonlinear restoring forces and Balhasar van der Pol studied electrical systems with nonlinear damping. Subsequently, any equation of the form

$$a\ddot{x} + b\dot{x} + f(x) = F \sin \omega t \quad (1)$$

was called Duffing's equation, the nonlinearity often being polynomial, usually cubic (Hayashi, 1964). Here, $\dot{x}$ represents the time derivative dx/dt .

Linear resonance has $f(x) = cx$ ($c > 0$), and Duffing's extension models many mechanical and electrical phenomena. With symmetry, f is odd, giving the first nonlinear approximation

$$f(x) = cx + dx^3. \quad (2)$$

If $d > 0$, the system is *hardening* and the resonant peak tilts to the right. A *softening* system ($d < 0$) has a peak tilted to the left (as in Figure 2). Duffing's method of successive approximation and a variety of averaging and perturbation techniques can estimate these tilts for conditions of weak nonlinearity.

Twin-Well Duffing Oscillator

Taking Equations (1) and (2) with $c < 0$, $d > 0$ gives the "twin-well" Duffing oscillator governed by the potential energy $V(x) = \frac{1}{2}cx^2 + \frac{1}{4}dx^4$. Trajectories lie in and across the two symmetric potential wells separated by the hill-top at $x = 0$. This is a useful archetypal model for studies of chaos (Guckenheimer & Holmes, 1983). The undamped, unforced system ($b = F = 0$) has two symmetrically placed orbits that (in infinite time) leave and return to the phase-space saddle at $x = 0$, $\dot{x} = 0$: we say they are "homoclinic to the saddle." For small b and F the corresponding invariant manifolds exhibit a homoclinic tangency on an arc in the (b, F) control space. Beyond this global bifurcation a homoclinic tangle generates "horseshoe dynamics" giving chaos and fractal basin boundaries (see Figure 3). The (b, F) arc can be estimated by Mel'nikov perturbation analysis.

Ueda's Chaos

For hardening with $c = 0$, Ueda (1980, 1992) mapped intricate regimes of subharmonics and chaos. Ueda's equation is

$$\ddot{x} + k\dot{x} + x^3 = B \cos t. \quad (3)$$

With $k = 0.05$, $B = 7.5$, all solutions settle onto a unique chaotic attractor, irrespective of $x(0), \dot{x}(0)$: its basin of attraction is the whole starting plane.

Figure 1. Waveform (a) shows a plot of $x(t)$ at the end of a long computer time integration during which any start-up transient is effectively dissipated, while the large fractal dot diagram (b) shows this chaotic attractor in a Poincaré section sampling $x(t)$ and $\dot{x}(t)$ stroboscopically at the period of the forcing. Two waveforms in (c) show the exponential divergence from two adjacent starts on the attractor where $(x(0), \dot{x}(0))$ are (3, 4) and (3.01, 4.01), respectively. Reproduced from Thompson & Stewart (2002) with the permission of John Wiley.

The steady chaotic response is shown in Figure 1. In each cycle, sheets of trajectories are folded and compressed, as in making flaky pastry. This mixing produces divergence (Figure 1(c)) that quickly makes adjacent motions totally uncorrelated, although both remain on the fractal attractor. This divergence serves to identify chaos: it is quantified by Lyapunov exponent techniques (Guckenheimer & Holmes, 1983).

Escape from a Potential Well

Asymmetric models were used by Hermann Helmholtz to model vibrations in the human ear. An archetypal example introduced by Thompson (1989) is

$$\ddot{x} + \beta \dot{x} + x - x^2 = F \sin \omega t. \tag{4}$$

This Helmholtz–Thompson equation governs escape from the well,

$$V(x) = \frac{1}{2}x^2 - \frac{1}{3}x^3. \tag{5}$$

Such escape is a universal problem in science, from activation energies of molecular dynamics to the

Figure 2. Three resonance response diagrams for Equation (4), where the maximum of the steady-state response, x_m , is plotted against the forcing frequency, ω , for fixed values of F (all with $\beta = 0.1$). At higher F , in (c), there is a regime with no attractor, implying inevitable escape from either fold A or the chaotic crisis ending the cascade from C. Reproduced from Thompson & Stewart (2002) with the permission of John Wiley.

gravitational collapse of massive stars. Failures in electrical systems are triggered when the underlying system escapes from a well: if power generators slip out of synchronization, an entire city can be blacked out. Naval research (Thompson, 1997) is directed toward the capsizing of vessels under sinusoidal forcing by ocean waves.

Equation (4) is used by Thompson & Stewart (2002) to illustrate a variety of complex phenomena including chaos, fractal boundaries, and indeterminacies. These arise in a wide class of systems involving nonlinear damping, different well shapes, different direct and parametric forcing, and hardening characteristics. They are not detected by perturbation and averaging methods.

Chaos in Nonlinear Resonance

Three response diagrams for Equation (4) are shown in Figure 2. The quadratic form of the restoring force is technically *softening* for $x > 0$ and *hardening* for $x < 0$, but its overall effect is *softening*. Thus in 2(a), the peaks tilt to the left, as for a cubic Duffing oscillator with

Figure 3. In the space of the coordinates $x(0)$, $\dot{x}(0)$, the four safe basins of attraction, (a)–(d), comprise all those starts that do not give escape: we see how they vary with f , the basin being dramatically eroded by fractal fingers at $f \approx 0.68$. This basin erosion is quantified in (e) by plotting the area of the safe basin against f to give an integrity diagram. Reproduced from Thompson & Stewart (2002) with the permission of John Wiley.

$d < 0$. At the low value of $F = 0.01$, where the small response is almost linear, the untitled peak lies over $\omega = 1$ (the natural frequency). At $F = 0.056$ we see the hysteresis response of a softening oscillator, with a jump to resonance at fold A as ω increases, and a jump from resonance at B as ω decreases. Between these *cyclic folds*, there are three steady periodic solutions with frequency ω : nonresonant attractor, S_N ; resonant attractor, S_R ; unstable saddle, D_F .

In 2(b), the resonant branch loses stability in a period-doubling cascade to chaos, and the jump at A is indeterminate.

Fractal Boundaries, Indeterminate Bifurcations

Transient motions arise from different starting values of $x(0)$, $\dot{x}(0)$, and Figure 3 shows how the safe basin of attraction varies with $f = F/F^E$. Here F^E is the steady-state escape magnitude, at which a slowly evolving system would jump out of the well. The observed fractal structure is generated at a homoclinic tangency. The sudden drop in the integrity diagram at the “Dover cliff” can be used as a design criterion. An

engineering system should not be operated at values of $f > 0.68$, even though there are still stable motions within the well up to $f = 1$ (Thompson & Stewart, 2002).

Fractal basin boundaries and their chaotic transients generate great complexities in all forms of Duffing’s equation once the response is significantly nonlinear: they are a topic of active research (Stewart et al., 1995). An example is the indeterminate jump from fold A in Figure 2(b). Locally, this is a normal saddle-node fold, but it is located precisely on a fractal boundary. The outcome from such a “tangled saddle-node” is unpredictable (Thompson & Soliman, 1991). Depending sensitively on how A is approached, the jump may settle onto attractor R or escape out of the well; it may also settle onto a co-existing subharmonic motion.

DUNE FORMATION

Dunes are sand formations, found on land, that have heights ranging from 1 to 500 m and have been shaped by the wind. These topographical structures are found typically where large masses of sand have accumulated, which can be in the desert or along the beach; thus, one distinguishes desert dunes and coastal dunes. Dunes can be mobile or fixed. Fixed dunes are older and are either “fossilized,” that is, transformed into a cohesive material, a precursor to sandstone, or fixed because of

Figure 1. Barchan dunes near Laâyoune, Morocco.

the vegetation or because the average wind over some period at their location is zero. Otherwise the sand moves if the winds are strong enough, which means typically stronger than 4 ms^{-1} .

The beautiful landscapes (Figure 1; see also color plate section) formed by dunes are characterized by very gentle hills interrupted by sharp edges called brink lines, delimiting regions of steeper slope, called slip-faces, lying in the wind shadow. Depending on the amount of available sand and the variation of the wind direction, one distinguishes different typical dune morphologies that have been classified by geographers into over a hundred categories. The most well known are longitudinal, transverse, and barchan dunes. Barchans (from an Arabic word) are crescent-shaped mobile dunes that appear when the wind always comes from the same direction and there is not much sand present. Their movement ranges from 5 to 50 m per year and is inversely proportional to their height. If sufficient sand is available to cover all the surface, then transverse dunes appear (from the merger of many barchans). Longitudinal dunes, that is, along the direction of the wind, are observed when the wind periodically changes its direction over about 30° . Other famous dune types are star dunes, ergs, parabolic dunes, and draas.

The driving force for sand motion is the drag imposed by the wind on the grains at the surface. A given dune morphology can therefore be understood as an aerodynamic instability close to a mobile surface. A complete mathematical description of the problem therefore needs the equation of motion of the wind velocity field coupled with an equation of motion of the granular surface. The right formulation of these equations requires a good understanding of the transport mechanism of sand.

Three types of transport can be distinguished according to the size of a sand grain: creep, saltation (bouncing), and suspension. The only mechanism relevant for dune formation is saltation, which drags grains typically of 100–300 μm diameter. The mechanism of saltation, first described by Ralph Bagnold in his pioneering work (Bagnold, 1941), consists of grains, which once lifted out from their granular bed are accelerated by the wind and then impact against the surface, ejecting new grains. These grains are again accelerated and eject a further splash

of grains, so that the number of grains flying above the surface increases exponentially until the total momentum transferred from the air to the grains saturates to its maximum capacity, and the wind can no longer pick up more sand from the dune. On dunes in the field, these saltating grains form a sheet of grains floating typically 5 cm above the surface. The wind typically is turbulent and has a logarithmic profile as a function of height, which (due to the presence of the grains) is strongly modified close to the surface. The height of the boundary layer is less than 1 cm. Using the techniques of Jackson & Hunt (1975), one can calculate the shear force of the wind at the surface in an approximate form and obtain reasonable agreement with measurements on dunes. The saturated flux of sand at the surface is a function of this shear stress and has been described by various phenomenological expressions, the first one given by Bagnold (1941) and subsequent ones by Lettau & Lettau (1969), and by Sørensen (1981). A full description also requires taking into account the transient length before (or after) reaching saturation. Together with mass conservation one can then close the system of equations, giving at the end a full set of equations of motions (Sauermaun et al., 2001).

When the local slope exceeds a value of typically 35° , the angle of repose, the sand begins to slide in the form of avalanches giving a second mechanism of sand transport driven by gravity. The slip-faces all have this slope. The edges separating them from the purely wind-driven regions are just given by the brink lines. Over these regions the wind field develops recirculation eddies of velocities typically below the minimum threshold for grain motion. When the saturation length is less than the size of these low-velocity regions, the sand grains get trapped. This is the principal instability underlying dune morphology: the dunes become traps of sand for more sand. The typical saturation length of about 10 m also means that no dune below 1.5 m in height is stable under Earth's meteorological conditions; the dune is too short for the air to reach its saturation point, and the dune suffers erosion.

Dunes have been studied on all continents and their shape, sand flux, velocity, and granulometry have been presented in many publications. Several

books review the subject (Pye & Tsoar, 1990). For different morphologies one finds specific shapes and scaling laws, but systematic studies exist only for barchans. Sand fluxes are typically measured with traps, but a more sophisticated metrology (e.g., acoustic, optic) is evolving. The limitation factors are the fluctuations of the wind fields and the climate. In the arid regions of the world, in particular the poor countries in the Sahara, dune motion poses an important threat to housing, roads, and fields, and sand removal constitutes a significant economic factor in these countries. Many empirical techniques of dune fixing and dune destruction have been developed, mostly applied to coastal dunes, which are in fact disappearing in many places, sometimes damaging the fragile dune ecosystem.

DYNAMICAL SYSTEMS

A dynamical system is a time-dependent, multicomponent system of elements with local states determining a global state of the whole system. In a planetary system, for example, the state of the system at a certain time is the set of values that completely describe the system (the position and momentum of each planet).

The states can also refer to moving molecules in a gas, excitation of neurons in a neural network, nutrition of organisms in an ecological system, supply and demand of economic markets, or behavior of social groups in human societies.

The dynamics of a system (the change of system states with time) is given by linear or nonlinear differential equations. In the case of nonlinearity, several feedback activities take place between the elements of the system: in the solar system, the movement of the Earth is determined by the gravitation not only of the Sun, but of all the other celestial bodies of the system, which attract each other gravitationally.

For deterministic processes (for example, movements in a planetary system), each future state is uniquely determined by the present state. A conservative (Hamiltonian) system such as an ideal pendulum is characterized by the reversibility of time direction and conservation of energy. Dissipative systems, for example, a real pendulum with friction, are irreversible. The time-dependent development of a system's state is geometrically represented by orbits (trajectories) in a state space or phase space, which is defined by the multidimensional vectors of the nonlinear system (*See Phase space*).

In addition to continuous processes, we can also consider discrete processes of changing states at certain points of time. Difference equations are important for modeling measured data at discrete points of time, which are chosen equidistant or defined by other measurement devices.

Random events (Brownian motion in a fluid, mutation in evolution) are represented by additional fluctuation terms. Classical stochastic processes, such as the billions of unknown molecular states in a fluid, are defined by time-dependent differential equations with distribution functions of probabilistic states. Stochastic nonlinear differential equations (such as Fokker-Planck equation, Master equation) are also used to model phase transitions of complex systems, including migration dynamics of populations, traffic dynamics, data dynamics in the Internet, among others.

In quantum systems, the dynamics of quantum states are determined by Schrödinger's equation. Although it is a deterministic differential equation of a wave function, its observables (position and momentum of a particle) depend on Heisenberg's uncertainty principle, which only allows probabilistic forecasts.

During the 17th–19th centuries, classical physics viewed the universe as a deterministic and conservative system. The astronomer and mathematician Pierre-Simon Laplace assumed that all future states of the universe could be computed or determined if all forces acting in nature and the initial states of all celestial bodies are known at one instant of time (Laplacian determinism). Laplace's assumption was correct for

linear and conservative dynamical systems such as a harmonic oscillator. However, at the end of the 19th century, Henri Poincaré discovered that celestial mechanics is not a completely computable system even if it is considered as a deterministic and conservative system. The mutual gravitational interactions of more than two celestial bodies (the many-body problem) correspond to nonlinear and non-integrable equations with instabilities and sometimes chaos (See **N-body problem**).

According to Laplacian determinism, similar causes effectively determine similar effects. Thus, in the phase space, trajectories starting close to each other also remain close to each other during time evolution. Dynamical systems with deterministic chaos exhibit an exponential dependence on initial conditions for bounded orbits: the separation of trajectories with close initial states increases exponentially. (The rate at which nearby orbits diverge from each other after small perturbations is measured by Lyapunov exponents.) Consequently, tiny deviations of initial states lead to exponentially increasing computational efforts for future data, limiting long-term prediction, although the dynamics is, in principle, uniquely determined.

The sensitivity of chaotic dynamics to small changes in initial conditions is known as the “butterfly effect”: small and local causes (local perturbations of the weather, for example) can lead to unpredictable large and global effects in unstable states (See **Butterfly effect**). According to the famous KAM theorem of Andrei Kolmogorov, Vladimir Arnol’d, and Jürgen Moser, trajectories in the phase space of classical mechanics are neither completely regular nor completely irregular, but depend sensitively on the chosen initial conditions. Changes of states in a dynamical system that change the stability of solutions to its nonlinear equations are associated with bifurcations of orbits in the corresponding phase space (See **Bifurcations**).

Dynamical systems can be classified by the effects of their dynamics on a region of the phase space. A conservative system is defined by the fact that, during time evolution, the volume of a region remains constant, although its shape may be transformed. An attractor is a region of a phase space into which all trajectories departing from an adjacent region, the so-called basin of attraction, converge. There are different kinds of more or less complex attractors. Chaotic attractors are highly complex structures of nonperiodic orbits in a bounded region of the phase space between regular behavior and stochastic behavior or noise. Although high-dimensional dynamical systems (such as the stock market, the economy, and society) cannot be formulated in all detail, approximate models may provide qualitative insights into their complex behavior.

DYNAMOS, HOMOGENEOUS

Dynamos convert mechanical energy into electromagnetic energy, the most familiar example being the bicycle dynamo. Nearly all electricity consumed by mankind is generated by dynamos in power plants—electrochemical processes also generate electric power, for example, in batteries, but these play only a minor role. The simplest dynamo is the disk dynamo originally invented by Faraday and shown in Figure 1. A metal disk rotates about its axis with an angular velocity $\Omega = k\omega$. When the disk is permeated by an initial magnetic field B_0 parallel to the axis, an electromotive force is generated between the axis and rim of the disk,

$$U = \Omega \cdot \int_{r_1}^{r_0} B_0 dr, \tag{1}$$

where r_1 and r_0 denote the radii of axis and disk. The electromotive force U can be used to drive an electric current J through the circuit indicated in Figure 1. Denoting by L and R the inductivity and the ohmic resistance of the circuit, we obtain for the current J

$$L \frac{dJ}{dt} + RJ = U. \tag{2}$$

The current J flowing through the circuit is associated with a magnetic field B_1 , which may replace the initial field B_0 . The integral $2\pi \int_{r_1}^{r_0} k \cdot B_1 dr / J$ describes

Figure 1. The disk dynamo.

the mutual inductivity M between circuit and disk. Equation (2) for the self-excited disk dynamo can thus be written in the form

$$L \frac{dJ}{dt} = (\Omega M / 2\pi - R) J, \quad (3)$$

which allows for exponentially growing solutions once the dynamo condition

$$\Omega > 2\pi R / M \quad (4)$$

is satisfied.

The disk dynamo is an inhomogeneous dynamo since it depends on an inhomogeneous distribution of electrical conductivity as given by the wiring of the circuit. The dynamo would not work if the sense of wiring around the axis would be opposite to that shown in the figure or if it would be short-circuited by immersion in a highly conducting fluid. While it is generally believed that planetary and stellar magnetic fields are generated by dynamos in the electrically conducting interiors of these celestial bodies, these dynamos must be homogeneous ones because they operate in singly connected finite domains of essentially homogeneous electrical conductivity. In 1919, Larmor first proposed this idea as an explanation for the magnetic field of sunspots. It was doubtful for a long time whether homogeneous dynamos were possible. Cowling proved in 1934 that axisymmetric fields could not be generated by a homogeneous dynamo. But, in 1958, Backus and Herzenberg independently demonstrated in a mathematically convincing way that homogeneous dynamos are indeed possible.

The velocity fields that are required to drive a homogeneous dynamo are necessarily more complex than the simple rotation velocity of the disk dynamo.

A new mathematical discipline called dynamo theory has evolved and continues to be an active field of research. One distinguishes between the kinematic dynamo problem based on a linear equation such as (3) with a prescribed velocity field and the magnetohydrodynamic dynamo problem in which the influence of the growing magnetic field on the velocity field is taken into account. Obviously, a magnetic field cannot grow exponentially forever. Just as the Lorentz force produced by the magnetic field together with the current density in the disk opposes the rotation of the disk in Figure 1, it also changes the velocity field of the magnetohydrodynamic dynamo. The external torque T_e applied to the disk in the figure must be increased in the presence of dynamo action in order to sustain the rotation rate Ω . The equilibrium strength of the magnetic field will thus be determined by the available torque T_e .

In the case of the geodynamo driven by convection flows in the liquid iron core of the Earth, as well as in the case of other planetary or stellar dynamos, the equations of motions together with the equation of magnetic induction (See **Magnetohydrodynamics**) must be solved to determine the strength of the generated magnetic field as a function of the relevant parameters. Extensive computer simulations have been performed in recent years. Some examples can be found in Jones et al. (2003). The complex numerical simulations of magnetohydrodynamic dynamos share the following properties with the simple disk dynamo:

(i) For given external parameters, there always exists a solution without magnetic field besides the dynamo solution, just as the disk of Figure 1 can rotate with $\Omega > \Omega_c$ in the absence of any initial field B_0 .

(ii) The existence of a dynamo solution requires that the magnetic Reynolds number Rm exceeds a critical value Rm_c . Rm is defined by

$$Rm = Vd\sigma\mu, \quad (5)$$

where V is a typical velocity, d is a characteristic length such as the radius of the iron core in the case of the Earth, and σ and μ are the electrical conductivity and the magnetic permeability of the fluid. The inverse product $\lambda = 1/\sigma\mu$ is called the magnetic diffusivity. The dimensionless parameter Rm corresponds to the quantity $\Omega M/R$ in the case of the disk dynamo. The nonmagnetic solution exists, but it is unstable for $Rm > Rm_c$.

(iii) Magnetohydrodynamic dynamos exist in two forms that are identical except for the sign of the magnetic field B . This property reflects the fact that the Lorentz force is given by an expression quadratic in B .

Property (iii) is the basic reason that the geomagnetic field has often switched its polarity in the geologic past. These "reversals" have occurred nearly randomly about

every 200,000 years on average. In contrast, the solar magnetic field reverses every 11 years in a surprisingly periodic fashion.

For the description of magnetic fields associated with a spherical system, one often uses the general representation for a solenoidal vector field,

$$\mathbf{B} = \nabla \times (\nabla h \times \mathbf{r}) + \nabla g \times \mathbf{r}, \quad (6)$$

in terms of a poloidal and a toroidal component each of which is described by a scalar function, the poloidal function h , and the toroidal function g . Without loss of generality, the averages of h and g over surfaces $|\mathbf{r}| = \text{constant}$ can be assumed to vanish. A homogeneous dynamo usually requires the interaction of both components of the magnetic field. It can be shown (Kaiser et al., 1994) that a magnetic field with vanishing toroidal part cannot be generated. It is also generally believed that a purely poloidal field cannot be generated either. But a proof of this hypothesis has not yet been given. The functions h and g can be separated into their axisymmetric parts $\bar{h}$ and $\bar{g}$ and non-axisymmetric parts, $\tilde{h} = h - \bar{h}$ and $\tilde{g} = g - \bar{g}$. The component $\bar{g}$ can easily be generated in a spherical dynamo through a stretching of the axisymmetric poloidal field by a differential rotation. This process is known as the ω -effect. The amplification of $\tilde{h}$ requires the interaction of the non-axisymmetric

components of magnetic fields and velocity fields. This is often called the α -effect. This latter effect can, of course, also be used for the generation of $\bar{g}$ in the absence of a differential rotation. Accordingly, one distinguishes between $\alpha\omega$ - and α^2 -dynamoes. These concepts were originally introduced within the framework of mean-field magnetohydrodynamics for which the reader is referred to the book by Krause & Raedler (1980).

ECONOMIC SYSTEM DYNAMICS

Economic dynamics is concerned with fluctuations in the economy. Most economic variables, such as gross domestic product (GDP), production, unemployment, interest rates, exchange rates, and stock prices, exhibit perpetual fluctuations over time. These fluctuations are characterized by sustained growth of production and employment as well as large oscillations in relative changes or growth rates. The fluctuations vary from fairly regular business cycles in macroeconomic variables to very irregular fluctuations, for example, in stock prices and exchange rates, in financial markets. In this note, we discuss some approaches to the theory of economic fluctuations, emphasizing the role of nonlinear dynamic models.

In contrast to many dynamic phenomena in natural sciences, uncertainty always plays a role in an economy, at least to some extent. Therefore, a purely deterministic model seems inappropriate to describe fluctuations in the economy, and a stochastic dynamic model is needed. Nevertheless, a key question in economic dynamics is whether a simple, nonlinear dynamic model can explain a *significant part* of observed economic fluctuations.

Brief History

There are two contrasting viewpoints concerning the explanation of observed economic fluctuations. According to the first (New Classical) viewpoint, the main source of fluctuations is to be found in exogenous, random shocks (news about economic fundamentals) to an inherently stable, often linear economic system. Without any external shocks to economic fundamentals (preferences, endowments,

technology, etc.), the economy would be stable and converge to the unique steady-state (growth) path. According to the second, opposing (Keynesian) viewpoint, economic fluctuations are not caused by chance or random impulses, but should be explained by nonlinear economic laws of motion. Even without any external shocks to the fundamentals of the economy, fluctuations in prices or other economic variables may arise. It is an old Keynesian theme that fluctuations are not determined by economic fundamentals only, but are also driven by volatile, self-fulfilling expectations ("animal spirits," market psychology).

The view that business cycles are driven by external random shocks was propagated in the 1930s, for example, by Ragnar Frisch and Jan Tinbergen (sharing the first Nobel Prize in Economic Sciences in 1969 "for having developed and applied dynamic models for the analysis of economic processes"). They observed that simple, linear systems buffeted with noise can mimic time series similar to those observed in real business cycle data. To several economists this approach was unsatisfactory, however, because it does not provide an *economic* explanation of business cycles, but rather attributes them to external, random events. In the 1940s and 1950s Nicholas Kaldor, John Hicks, and Richard Goodwin developed nonlinear dynamic models with locally unstable steady states and stable limit cycles as an explanation for business cycles. These early nonlinear business cycle models, however, suffered from a number of serious shortcomings. First of all, the laws of motion were too "ad hoc," and in particular they were *not* derived from rational behavior, that is, from utility and profit maximizing principles. Secondly, the simulated time series from the models were too regular compared with observed business cycles, even when small dynamic noise was added to the models. Finally, expectation rules were "ad hoc," and along the regular cycles, agents made "systematic" forecasting errors.

The Role of Expectations

The most important difference between economics and natural sciences is perhaps the fact that an economic system is an *expectations feedback* system. Decisions

of economic agents are based upon their expectations and beliefs about the future state of the economy. Through these decisions, expectations feed back into the economy and affect actual realization of economic variables. These realizations lead to new expectations, in turn affecting new realizations, implying an infinite sequence of expectational feedback. For example, in the stock market, optimistic expectations that stock prices will rise will lead to a larger demand for stocks, which will cause stock prices to rise. This process may lead to a self-fulfilling speculative bubble in the stock market. A theory of expectation formation is, therefore, a crucial part of economics, in particular for modeling dynamic asset markets.

In the early business cycle models, simple, ad hoc expectations rules were employed, such as naive expectations (where the forecast of the economic variable is simply the latest observation of that variable) or adaptive expectations (where the forecast is a weighted average of the previous forecast and the latest observation). An important problem with simple forecasting rules is that typically agents make systematic forecasting errors, especially when there are regular cycles. A smart agent would learn from her mistakes and adapt her expectations rule accordingly. Another problem is that if an agent is to use a simple forecasting rule, it is far from clear which simple rule to choose in a particular model. With the development of empirical, econometric analysis of business cycles, it became clear that unrestricted models of expectations preclude a systematic inquiry into business fluctuations. These considerations led to the development of *rational expectations*, a solution to the expectations feedback system proposed by John Muth (1961) and applied to macroeconomics, for example, by Robert Lucas and Thomas Sargent. Rational expectations means that agents use all available information, including economic theory, to form optimal forecasts and that, on average, expectations coincide with realizations. In a deterministic model, without noise and randomness, rational expectations implies perfect foresight (no mistakes at all); in a stochastic model, rational expectations coincides with the conditional mathematical expectations given all available information (no mistakes on average, no systematic bias).

In the 1970s and 1980s, the rational expectations critique culminated in the development of New Classical economics and real business cycle models, based upon rational expectations, intertemporal utility and profit maximization, and perfectly competitive markets. This approach outdated the early Keynesian nonlinear business cycle models of the 1950s. Due to the discovery of deterministic chaos and other developments in nonlinear dynamics, however, the last two decades have witnessed a strong revival of interest in nonlinear endogenous business cycle models.

Nonlinear Dynamics

In mathematics and physics, things changed dramatically in the 1970s due to the discovery of deterministic chaos, the phenomenon that simple, deterministic laws of motion can generate unpredictable time series. This discovery shattered the Laplacian deterministic view of perfect predictability and made scientists realize that long-run prediction may be fundamentally impossible, even when laws of motion are known exactly. Inspired by "chaos theory," economists (e.g., Richard Day and Jean-Michel Grandmont) started looking for nonlinear, deterministic models generating erratic time series similar to the patterns observed in real business cycles. This search led to new, simple nonlinear business cycle models within the paradigm of rational expectations, optimizing behavior and perfectly competitive markets, generating chaotic business fluctuations.

In the 1980s, several economists (e.g., William Brock, Davis Dechert, Jose Scheinkman, and Blake LeBaron) also employed nonlinear methods, such as correlation dimension tests, from the natural sciences to look for evidence of nonlinearity and low deterministic chaos in economic and financial data. This turned out to be a difficult task because the methods employed require very long time series and the methods are very sensitive to noise. One can say that evidence for low-dimensional deterministic chaos in economic and financial data is weak (but it seems fair to add that because of the sensitivity to noise, the hypothesis of chaos buffeted with dynamic noise has not been rejected) but evidence for nonlinearity is strong. In particular, Brock, Dechert, and Scheinkman have developed a general test (the BDS-test), based upon ideas from U-statistics theory and correlation integrals, to test for nonlinearity in a given time series; see Brock et al. (1996) and Brock, Hsieh, & LeBaron (1991) for the basic theory, references, applications, and extensions. The BDS test has become widely used in economics and also in physics.

Bounded Rationality

Already in the 1950s, Herbert Simon pointed out that rationality requires unrealistically strong assumptions about the computing abilities of agents and proposed that *bounded rationality*, with limited computing capabilities and with agents using habitual rules of thumb instead of perfectly optimal decision rules, would be a more accurate description of human behavior. Nevertheless, as noted above, rational expectations became the dominating paradigm in dynamic economics in the 1970s and 1980s. Nonlinear dynamics, the possibility of chaos, and its implications for limited predictability shed important new light on the expectations hypothesis, however. In a simple (linear) stable economy with a unique steady-state path, it seems natural that

agents can learn to have rational expectations, at least in the long run. A representative, perfectly rational agent model nicely fits into a linear view of a globally stable and predictable economy. But how could agents have rational expectations or perfect foresight in a complex, nonlinear world, with prices and quantities moving irregularly on a strange attractor and sensitivity to initial conditions? A boundedly rational world view with agents using simple forecasting strategies, perhaps not perfect but at least approximately right, seems more appropriate for a complex nonlinear world. These developments contributed to a rapidly growing interest in bounded rationality in the 1990s (see, e.g., the survey in Sargent (1993)). A boundedly rational agent forms expectations based upon observable quantities and adapts her forecasting rule as additional observations become available. Adaptive learning may converge to a rational expectations equilibrium, or it may converge to an "approximate rational expectations equilibrium," where there is at least some degree of consistency between expectations and realizations (see, e.g., Evans & Honkapohja (2001) for an extensive and modern treatment of adaptive learning in macroeconomics).

Interacting Agents and Evolutionary Models

The representative agent model has played a key role in economics for a long time. An important motivation for the dominance of the rational agent model dates back to the 1950s, to Milton Friedman who argued that nonrational agents will be driven out of the market by rational agents, who will trade against them and simply earn higher profits. In recent years, however, this view has been challenged, and heterogeneous agent models are becoming increasingly popular, especially in financial market modeling (see, e.g., Kirman (1992) for a critique on representative agent modeling).

Many heterogeneous agent models are artificial, computer simulated markets. This work views the economy as a complex evolving system composed of many different, boundedly rational, interacting traders, with strategies, expectations and realizations co-evolving over time (see, e.g., work at the Santa Fe Institute collected in Anderson et al. (1988)). Two typical trader types arising in many heterogeneous agent financial market models are fundamentalists and chartist or technical traders. Fundamentalists base their investment decisions upon market fundamentals such as dividends, earnings, interest rates, or growth indicators. In contrast, technical traders pay no attention to economic fundamentals but look for regular patterns in past prices and base their investment decision upon simple trend following trading rules. An evolutionary competition between these different trader types, where traders tend to follow strategies that have performed well in the recent past, may lead to irregular switching between the different strategies and result in complicated, irregular

asset price fluctuations. It has been shown, for example, by Brock and Hommes (1997, 1998), that in these evolutionary systems, rational agents and/or fundamental traders do not necessarily drive out all other trader types, but that the market may be characterized by perpetual evolutionary switching between competing trading strategies. Nonrational traders may survive evolutionary competition in the market (see, e.g., Hommes (2001) for a survey and many relevant references). Lux & Marchesi (1999) show that these types of interacting agent models are able to generate many of the stylized facts, such as unpredictable returns, clustered volatility, fat tails, and long memory, observed in real financial markets.

Future Perspective

A good feature of the rationality hypothesis is that it puts natural discipline on agents' forecasting rules and minimizes the number of free parameters in dynamic economic models. In contrast, the "wilderness of bounded rationality" leaves too many degrees of freedom in modeling, and it is far from clear which out of a large class of habitual rules of thumb is most reasonable. Stated differently in a popular phrase: "there is only one way (or perhaps a few ways) one can be right, but there are many ways one can be wrong." The philosophy underlying the evolutionary approach is to use simple forecasting rules based upon their performance in the recent past. In this type of modeling, "evolution decides who is right." Bounded rationality, heterogeneity, adaptive learning, and evolutionary competition all create natural nonlinearities. Nonlinearity is, therefore, likely to play an increasingly important role in the future of economic dynamics.

EFFECTIVE MASS

Effective mass is a physical quantity characterizing the dynamics of a particle or quasiparticle with an energy ($\mathcal{E}$) that is quadratic in the components of the momentum ($\mathbf{p}$). With a dispersion relations of the form

$$\mathcal{E} = \mathcal{E}_0 + \frac{1}{2} \mu_{ik} p_i p_k, \quad \mathcal{E}_0 = \text{const.}, \quad (1)$$

the tensor $\mu_{ik} = m_{ik}^{-1}$ is a tensor of reciprocal effective masses, and m_{ik} is an effective mass tensor. Considering Equation (1) as the Hamiltonian function of a free particle, one can determine a particle velocity using a canonical equation of motion

$$v_i = \partial \mathcal{E} / \partial p_i, \quad i = 1, 2, 3. \quad (2)$$

From the Hamiltonian function (1) and relations (2) a Lagrangian function of the particle is

$$L = L_0 + \frac{1}{2} m_{ik} v_i v_k, \quad L_0 = \text{const.} \quad (3)$$

As the Lagrangian function of a free particle coincides with its kinetic energy, the effective mass tensor can be associated with kinetic energy (3), which is quadratic in components of the velocity.

Having its origin in the mechanics of particles, the definition of the effective mass can be connected with the dynamics of wave packets. According to the de Broglie principle of wave-corpuscular dualism, the energy $\mathcal{E}$ and momentum $\mathbf{p}$ of a particle correspond to the frequency ω and wave vector $\mathbf{k}$ of some wave packet, as $\mathcal{E} = \hbar\omega$ and $\mathbf{p} = \hbar\mathbf{k}$ where $\hbar$ is Planck's constant. From this point of view, any quasiparticle excitation in condensed matter behaves as a particle-like wave packet, and Equation (2) coincides with the definition of a group velocity of the wave packet.

The effective mass tensor for a free Newtonian particle or quasiparticle in an isotropic media (for example, excitations in the superfluid liquid He) has the simple form: $m_{ik} = m \delta_{ik}$, $i, k = 1, 2, 3$.

The dispersion relation of type (1) for the quasiparticles described by band theory in a periodic structure (electrons in metals and phonons in crystals) takes place at vicinities of singular points in the $\mathbf{p}$ -space. These are at the points where energy $\mathcal{E}(\mathbf{p})$ has a minimum (then μ_{ik} is positively definite), at the points near the maximum of $\mathcal{E}(\mathbf{p})$ (then μ_{ik} is negatively definite), and at the so-called conical points, when the main values of the tensor μ_{ik} have different signs.

In the general band theory of electrons and semiconductors, energy is a more complicated (arbitrary) function of the momentum $\mathcal{E} = \mathcal{E}(\mathbf{p})$, and the tensor of the reciprocal effective mass is defined as

$$\mu_{ik} = \frac{\partial^2 \mathcal{E}}{\partial p_i \partial p_k}, \quad i, k = 1, 2, 3, \quad (4)$$

which can be a function of the momentum. The effective mass tensor allows one to calculate the acceleration of a particle under the action of the external force $\mathbf{f}$. As an equation of the particle motion is

$$\frac{d\mathbf{p}}{dt} = \mathbf{f}, \quad (5)$$

Equations (2) and (5) lead to the following equation for the acceleration:

$$m_{ik} \frac{dv_k}{dt} = f_i, \quad i = 1, 2, 3. \quad (6)$$

The force $\mathbf{f}$ is determined, for example, by the electric field effect on a charged particle.

The effective mass has another definition for an electron (or a charged particle) moving in a static magnetic field $\mathbf{B}$. In such a case the force $\mathbf{f}$ is

a Lorentz force, and Equation (5) implies that the electron moves under the following conditions: $\mathcal{E}(\mathbf{p}) = \text{constant}$ and $p_B = \text{constant}$, where p_B is a projection of the momentum on the magnetic field direction. Thus, an electron trajectory in $\mathbf{p}$ -space is a section of the isoenergy surface $\mathcal{E}(\mathbf{p}) = \mathcal{E}$ with the plane $p_B = p$. If this section is a closed curve and has a sectional area $S(\mathcal{E}, p)$, the electron motion is periodic in time and characterized by the "cyclotron frequency" $\omega_c = eB/(m^*c)$, where e is the electron charge, and c is the velocity of light. Thus, the effective mass m^* is equal to

$$m^* = \frac{1}{2\pi} \frac{\partial S}{\partial \mathcal{E}}. \quad (7)$$

Cyclotron resonance is the most convenient experimental method for measuring the effective mass defined in Equation (6).

EINSTEIN EQUATIONS

After Albert Einstein (1905) published his special theory of relativity, Hermann Minkowski (1908) delivered a seminar in which he said

Henceforth space by itself, and time by itself, are doomed to fade away into mere shadows, and only a kind of union of the two will preserve an independent reality.

This "kind of union" is called space-time. In special relativity, two observers in inertial frames moving at constant velocity with respect to each other will not, in general, agree on the distance between two objects

or the duration of some interval of time they both observe. However, suppose an observer sees a particle at time t and at (cartesian) coordinates (x, y, z) and later observes the particle at time $t + dt$ to be at the point $(x + dx, y + dy, z + dz)$. If both observers record these measurements, they will both agree on the value of the quantity

$$ds^2 = c^2 dt^2 - dx^2 - dy^2 - dz^2 \quad (1)$$

(where c is the speed of light in vacuum), which is called the metric on Minkowski space-time. In tensor notation, $ds^2 = \sum \eta_{\mu\nu} dx^\mu dx^\nu$, where the four values of the subscripts μ, ν correspond to the coordinates on the four-dimensional space-time, and $\eta_{\mu\nu} = \text{diag}(1, -1, -1, -1)$ is the metric tensor. Minkowski space-time is flat; that is, it can be identified with its tangent space.

In general relativity, described by the Einstein equations, the constants $\eta_{\mu\nu}$ are replaced by more general, coordinate-dependent metric coefficients $g_{\mu\nu}$, and space-time is allowed to have nonzero curvature. This curvature manifests itself as gravitation and is caused by the presence of matter. In any space-time, test particles follow geodesics (paths that minimize distance locally, i.e., generalizations of straight lines) of the space-time. In the now-famous words of the astrophysicist John Archibald Wheeler (Misner, Thorne & Wheeler, 1973),

Matter tells space-time how to curve and curved space tells matter how to move.

The latter part of the sentence corresponds to the geodesics; the first part is the content of the Einstein equations, which in tensor notation are

$$G_{\mu\nu} = 8\pi T_{\mu\nu}, \quad \mu, \nu = 0, 1, 2, 3, \quad (2)$$

where we are using units in which the speed of light and Newton's gravitational constant both have the value 1. The tensor $T_{\mu\nu}$ is called the stress-energy or energy-momentum tensor, and its components measure several physical properties of continuous matter. In vacuum, $T_{\mu\nu} = 0$. The tensor $G_{\mu\nu}$ is called the Einstein tensor. It is constructed from $g_{\mu\nu}$ and its first two derivatives, and it is a measure of the curvature of space-time. In short, the left-hand side of the Einstein equations (2) measures curvature, which encodes the geometry of the space-time, while the right-hand side of the equations measures energy, momentum, and stress, and so encodes the physical properties of the matter. The Einstein equations can be derived from an action principle and are constructed in such a way as to satisfy a generalization of the law of conservation of energy.

Apart from the flat space-time of Minkowski, the most important solutions of the Einstein equations

are those with spherical symmetry. In Schwarzschild coordinates, the metric of any vacuum, asymptotically flat, spherically symmetric space-time has the form

$$ds^2 = \left(1 - \frac{2M}{r}\right) dt^2 - \left(1 - \frac{2M}{r}\right)^{-1} dr^2 - r^2(d\theta^2 + \sin^2\theta d\phi^2), \quad (3)$$

where M is a constant (Schwarzschild, 1916). The Schwarzschild metric (3) is used to describe the external field of a nonrotating spherically symmetric matter distribution (such as a star) of mass M . Expression (3) becomes singular at the so-called Schwarzschild radius $r = 2M$. In ordinary stellar models, the Schwarzschild radius lies deep in the interior of the star where the vacuum metric (3) does not apply. However, if a star undergoes gravitational collapse, then its radius shrinks to zero and the Schwarzschild radius is in the vacuum region.

By computing certain curvature invariants, it can be shown that there is no physical singularity at $r = 2M$. In other words, there is nothing wrong with the space-time manifold at $r = 2M$; it is simply that the coordinates r and t are bad here. This phenomenon is called a coordinate singularity. Use of the so-called Kruskal–Szekeres coordinates allow us to explicitly extend the space-time past this singularity. The surface $r = 2M$ is the event horizon of a black hole. Nothing can escape from the interior of the event horizon, including light, and will eventually fall into the (physical) singularity at $r = 0$ in finite proper time, where the theory breaks down.

Although a great number of exact solutions of the Einstein equations are known (Stephani et al., 2003), they describe very special and often unphysical situations. In order to study more general situations, extensive numerical studies have been undertaken. There are many ways in which the numerical evolution of the Einstein equations is especially difficult. The dependent variables of the Einstein equations are metric coefficients which describe the space-time manifold on which the independent variables (the space-time coordinates) live. Many issues stem from the fact that there is no preferred frame in general relativity meaning that one has to deal with the choice of an appropriate gauge and to recognize and avoid coordinate singularities. The Einstein equations are a system of ten strongly coupled nonlinear PDEs.

The Einstein equations as written in (2) are not in evolution form. For numerical purposes the Einstein equations are usually written in terms of an evolution variable λ . A Cauchy or characteristic approach corresponds to the normal of the $\lambda = \text{const}$ hypersurfaces being time-like or null, respectively. Einstein's equations then project to a set of constraint equations on the hypersurfaces and a set of evolution equations. If the constraint equations are satisfied on

an “initial” hypersurface, then they are preserved under evolution to other hypersurfaces.

Numerical studies using the Cauchy approach have been used to model the collision of axisymmetric black holes (Anninos et al., 1995), and they have led to the discovery of critical phenomena in spherical collapse (Choptuik, 1993). One drawback of this method is that boundary conditions are usually artificially imposed on the hypersurfaces to avoid integrating out to infinity (although sometimes conformal methods can be used to include space-like infinity). The characteristic approach has led to the first unlimited evolution of a single black hole space-time (Gomez et al., 1998). While this approach allows for long-time simulations, it is only valid in the absence of crossing characteristics or caustics.

General relativity makes a number of predictions that have been tested. These include the excess advance in the perihelion of Mercury, the bending of light rays near the sun, time delays in radar signals passing near the sun, and gravitational lensing of distant galaxies by nearer ones. The most important prediction still awaiting confirmation is the existence of gravitational waves. A number of detectors have now been built around the world and observations are expected soon.

ELASTIC AND INELASTIC COLLISIONS

See **Collisions**

ELECTROENCEPHALOGRAPH AT LARGE SCALES

Since the first human scalp recordings of the tiny electric currents generated by the brain (electroencephalogram or EEG) were obtained in the mid-1920s, EEG has been recognized as a genuine (if often opaque) window on the mind, allowing observations of brain processes to be correlated with behavior and cognition. EEG has important applications in medicine, including epilepsy, head trauma, drug overdose, brain infection, sleep disorder, coma, stroke, tumor, monitoring anesthesia depth, and fundamental cognitive studies. Most EEG power occurs at frequencies below about 15 Hz in scalp (not cortical) recordings. EEG and magnetoencephalography (MEG) are the only technologies with sufficient temporal resolution to follow the fast dynamic changes associated with cognition; however, EEG spatial resolution is poor relative to modern brain structural imaging methods such as positron emission tomography (PET), computed tomography (CT), and magnetic resonance imaging (MRI). Each scalp electrode records electrical activity at very large scales, involving cortical tissue containing perhaps 10^7 – 10^9 neurons.

Mesoscopic and Microscopic Sources

Scalp potentials are generated by micro-current sources at cell membranes. Sorting out the complex relations between micro-sources and macroscopic scalp potentials is facilitated by assuming an intermediate (mesoscopic) descriptive scale that recognizes the columnar structure of the neocortex. From this perspective, the mesoscopic source strength of a volume of tissue is its electric current dipole moment per unit volume (microamps/mm²), designated as $\mathbf{P}(\mathbf{r}', t)$. This function represents the weighted average of micro-source activity in a volume of the neocortex (near $\mathbf{r}'$) that is large compared with the scale of individual neurons yet small compared with the size of a typical EEG electrode. For the idealized case of micro-sources of one sign confined to a superficial cortical layer and micro-sources of opposite sign confined to a deep layer, $\mathbf{P}(\mathbf{r}', t)$ is roughly the mesoscopic current density across a cortical column (≈ 1 mm²). The contributing electrical activities are primarily dendritic post-synaptic currents, although currents associated with axonal action potentials (spikes) may also contribute (see Figure 1).

Mesoscopic Sources and Scalp Recordings

Human neocortical sources form dipole layers over which the function $\mathbf{P}(\mathbf{r}', t)$ varies with cortical location ($\mathbf{r}'$), measured in and out of cortical folds. In a few special cases, $\mathbf{P}(\mathbf{r}', t)$ may be approximated by a few cm-scale active regions, consisting of focal sources as in focal epilepsy or mid-latency components of evoked

Figure 1. A mesoscopic tissue mass (for example, a mm-scale cortical column containing millions of volume micro-current sources $s(\mathbf{r}', \mathbf{w}, t)$) produces a current dipole moment per unit volume $\mathbf{P}(\mathbf{r}', t)$, or meso-source strength. Cortical or scalp potential due to brain sources is the weighted integral of $\mathbf{P}(\mathbf{r}', t)$ over the brain volume or, in the case of exclusively cortical sources, the integral over the cortical surface.

potentials (before tangential spread to other cortical locations). In general, however, $\mathbf{P}(\mathbf{r}', t)$ is widely distributed, perhaps over the entire cortical surface. Most EEGs are believed to be generated as a linear sum of contributions from cortical sources, in which case cortical or scalp potential may be approximated by the following integral of dipole moment over the cortical surface:

$$\Phi(\mathbf{r}, t) = \int_S \mathbf{G}(\mathbf{r}, \mathbf{r}') \cdot \mathbf{P}(\mathbf{r}', t) dS(\mathbf{r}'). \quad (1)$$

The Green function $\mathbf{G}(\mathbf{r}, \mathbf{r}')$ contains all geometric and conductive information about the head volume conductor. Cortical dipole moment may in turn be expanded in a series of basis functions $\mathbf{p}_n(\mathbf{r})$:

$$\mathbf{P}(\mathbf{r}, t) = \sum_{n=0}^{\infty} \xi_n(t) \mathbf{p}_n(\mathbf{r}). \quad (2)$$

An idealized model neocortex consists of a thin spherical shell with $\mathbf{P}(\mathbf{r}', t)$ everywhere normal to the surface, reflecting the columnar structure of the closed neocortical surface. An appropriate choice of basis functions for this idealized cortex is the set of spherical harmonics $Y_{lm}(\theta, \phi) \mathbf{a}_r$, where $\mathbf{a}_r$ is a unit vector in the radial direction and (θ, ϕ) are the usual spherical coordinates. The single sum over n in Equation (2) may then be expressed as a double sum $l = 0, \infty; m = -l, +l$, associated with the spherical geometry. Combining Equations (2) and (1) yields the following series expansion for the cortical $\mathbf{r}_C$ or scalp $\mathbf{r}_S$ surface potential $\Phi(\mathbf{r}, t)$ in terms of a new set of basis functions $\phi_n(\mathbf{r})$ that are surface integrals of the dot product of the Green's function $\mathbf{G}(\mathbf{r}, \mathbf{r}')$ with the

basis functions $p_n(\mathbf{r})$. Thus,

$$\Phi(\mathbf{r}, t) = \sum_{n=0}^{\infty} \xi_n(t) \phi_n(\mathbf{r}). \quad (3)$$

General Dynamic Properties of Cortical and Scalp Potentials

As summarized below, EEG exhibits many dynamic behaviors, depending on recording location, physiologic state, and subject.

- (i) Often complex physical or biological systems can be adequately characterized by only a few terms in Equation (3). The time-dependent coefficients $\xi_n(t)$ are called order parameters in the field of synergetics and may be governed by nonlinear differential or integral equations. The basis functions $\phi_n(\mathbf{r})$ may be chosen (bottom up) by physiological theory or (top down) by experimental data, for example, by constructing Karhunen–Loève expansions (also called principal components analysis) in which the $\phi_n(\mathbf{r})$ are chosen as the most efficient set of orthogonal functions representing a data record.
- (ii) The basis functions $\phi_n(\mathbf{r})$ are typically ordered in terms of progressively higher spatial frequencies as in Fourier series. The index n is then a measure of the two-dimensional spatial frequency of the corresponding basis function. Many systems exhibit a correspondence between spatial and temporal frequencies such that Fourier transforms of the order parameters $\xi_n(\omega)$ peak at higher frequencies ω for higher spatial frequencies n . For linear wave phenomena, such a correspondence is called the dispersion relation.
- (iii) The large-scale spatiotemporal dynamics of cortical potential $\Phi(\mathbf{r}_c, t)$ are believed to be very similar to the dynamics of the mesoscopic cortical sources $\mathbf{P}(\mathbf{r}, t)$. The head volume conductor acts as a low-pass spatial filter, resulting mainly from the low electrical conductivity of skull and the physical separation (1–2 cm) between sources and electrodes. Scalp potential $\Phi(\mathbf{r}_s, t)$ is then a spatial low-pass representation of cortical potential $\Phi(\mathbf{r}_c, t)$ or mesoscopic source function $\mathbf{P}(\mathbf{r}, t)$. Comparisons of cortical potential (ECoG) with scalp potential (EEG) show that this spatial filtering results in temporal filtering. That is, the Fourier transform of cortical potential $\Phi(\mathbf{r}_c, \omega)$ typically contains much more relative power at higher frequencies (say 15–40 Hz) than the scalp potential transform $\Phi(\mathbf{r}_s, \omega)$, recorded in the same brain state, an observation qualitatively consistent with normal wave dispersion relations.
- (iv) EEG phenomena typically exhibit larger amplitudes at lower frequencies. In deep sleep and mod-

erate to deep anesthesia, $\Phi(\mathbf{r}_s, t)$ is typically a few 100 μV with nearly all power in the delta range (0–4 Hz) at all scalp locations. The eyes closed, waking alpha rhythm (ca. 40 μV) is normally dominated by one or two spectral peaks in the 8–13 Hz range at widespread scalp locations. Low-amplitude beta activity (ca. 13–20 Hz) superimposed on alpha rhythms is more evident in frontal cortex. Alcohol and hyperventilation typically lower alpha frequencies and increase amplitudes; barbiturates increase beta activity. Scalp EEG activity is more consistent with limit cycle modes $\xi_n(t)$ than low-dimensional chaos.

- (v) Scalp EEG is a weighted space average of many cortical rhythms that can look different in different cortical regions. Alpha rhythms have been recorded from nearly the entire upper cortical surface, including frontal and prefrontal areas. Differences in ECoG waveforms between cortical areas are largely eliminated with anesthesia, suggesting shifts from more functional localization to more globally dominated brain states.
- (vi) Both globally coherent and locally dominated behavior can occur within the alpha band, depending on narrow band frequency, measurement scale and brain state. Upper alpha (ca. 10 Hz) and theta (ca. 4–6 Hz) phase locking between cortical regions during mental calculations often occurs, consistent with neural network formation. At the same time, quasi-stable alpha phase structures consistent with global standing waves have been observed.

Neocortical Dynamic Theory

The apparent balance among locally and globally dominated dynamic processes has been estimated by phase synchronization among other measures. Cortical or thalamic interactions with time delays due to rise and decay times of post-synaptic potentials (local theory) have been modeled. Network frequencies are then determined only by local tissue properties. In global theories, characteristic frequencies depend on the entire neocortex/cortico-cortical fiber system. Excitatory synaptic action density $F(\mathbf{r}, t)$ may be expressed in terms of action potential density $\Gamma(\mathbf{r}, t)$ by

$$F(\mathbf{r}, t) = \int_0^{\infty} dv \int_S R(\mathbf{r}, \mathbf{r}_l, v) \times \Gamma\left(\mathbf{r}_l, t - \frac{|\mathbf{r} - \mathbf{r}_l|}{v}\right) dS(\mathbf{r}_l) \quad (4)$$

The outer integral is over distributed cortico-cortical propagation speeds v , and the inner integral is over the neocortical surface S . The dependence of cortico-cortical fiber density with distance $|\mathbf{r} - \mathbf{r}_l|$ is expressed by the function $R(\mathbf{r}, \mathbf{r}_l, v)$. This linear relation between the dependent variables $F(\mathbf{r}, t)$ and $\Gamma(\mathbf{r}, t)$ may

be combined with a variety of nonlinear local equations in the same dependent variables. Such local/global theories include both network-to-global and global-to-network interactions.

ELECTROENCEPHALOGRAPH AT MESOSCOPIC SCALES

The two most dominant theoretical positions that have influenced the development of explanations of behavior are functional modularity, where specific behaviors are believed to reside in distinct cortical locations, and mass action, in which behavior is posited to arise out of the cooperative activity of distributed neural structures comprising the brain. The first of these positions predominates in the medical and cognitive sciences, based upon observations collected over many years in which selective behavioral deficits were observed to occur in response to the specific destruction or stimulation of various areas of the brain. This has led to considering the brain as a collection of interconnected functionally specialized modules. This view is generally known as modularism and in the context of higher functions is also referred to

as cortical localizationism. Modules are thought to embody algorithms, acting mechanistically on input to produce output, in a computer-like manner. Mass action, however, considers behavior as best understood as arising out of cooperative neural activity occurring over a number of interacting spatial and temporal scales. The consequence of this view is that behavior can now be characterized by the observation of dynamical patterns of brain activity.

The dynamics of the brain can be observed at a number of different spatial and temporal scales. These range from the level of the ion channel, synapse, and neuron (microscopic), to the level of neuronal population (mesoscopic), up to the level of large aggregates of brain tissue (macroscopic). The associated methods can generally be divided into those that measure some form of electromagnetic activity and those that reflect the metabolic correlates of neural activity. At the mesoscopic scale electromagnetic measures typically have millisecond temporal resolution whereas metabolic measures (e.g., fMRI, PET, near-infrared spectroscopy, diffuse optical tomography) have comparatively poor temporal resolution (s), while both mesoscopic and metabolic measures have comparable spatial resolution (mm). Electromagnetic measurements of brain activity better reflect the time scales of neuronal activity associated with the dynamics of behavior. For these reasons theories of mesoscopic brain dynamics are built around state variables that characterize the electromagnetic activity associated with neural populations. The most important mesoscopic electromagnetic measures are those of the local field potential (LFP) and the electrocorticogram (ECoG) which predominately reflect the quasi-static electromagnetic fields produced in response to the ionic currents generated by synchronized synaptic activity. It is generally thought that in the cortex this synchronized activity is linearly related to the spatially averaged soma membrane potential of populations of excitatory (pyramidal) neurons.

For both excitatory and inhibitory neuronal populations the mean soma membrane potential determines the mean rate of neuronal action potential generation (or firing rate). In the simplest case, the mean population firing rate is a sigmoidal function of the mean soma membrane potential for functionally equivalent members of the same neuronal population. More generally, such a relationship will be time-variant. Because the mean soma membrane potential is a function of neuronal population synaptic input which itself is a function of the mean neuronal population firing rates, the mean soma membrane potential can be used as a canonical state variable to both characterize and develop theories of the dynamics of neuronal populations.

At the level of the neuronal population, the spatially averaged soma membrane potential is typically defined over the characteristic scales of the short-range

Figure 1. The neurons of mammalian cortex interact with each other locally (by short range connections) and globally (by long-range connections). Short-range connections serve to diffusely interconnect the intermixed excitatory (e) and inhibitory (i) neuronal populations of cortex. The characteristic scales of these connections loosely organize cortex into a sheet of overlapping “modules” or cylinders that span the entire thickness of cortex. The resulting pattern is often referred to as columnar organization with a single one of these cylinders known as a cortical macrocolumn. One way of quantifying the strength of interaction between these local neuronal populations is to specify the mean number of connections (or synapses) neurons of one population receive from neurons of the same or another population (b_{ij}).

intracortical fibers. These intracortical fibers comprise the recurrent axonal branchings of the pyramidal neurons as well as all the axonal fibres of the inhibitory interneurons. Detailed morphometric studies of cortex have established that the typical characteristic spatial scale of these fibers ranges anywhere between $30\ \mu\text{m}$ to $1\ \text{mm}$ (Braitenberg & Schüz, 1998). The advantage of using this spatially averaged state variable is that it has a commensurate spatial scale to LFP and ECoG recordings.

Most mesoscopic theories of neuronal dynamics have considered cerebral cortex to consist of two functionally distinct neural populations—excitatory (e) and inhibitory (i)—reflecting the respective pyramidal and interneuron populations. The earliest models of cortical mass action attempted to describe neuronal dynamics exclusively in terms of short- and long-range excitatory interactions between excitatory populations. While a number of interesting analytical solutions were obtained using this approach, they are no longer of any significant physiological relevance because they did not incorporate the activity of inhibitory neurons. Subsequent models, based on anatomical considerations, have addressed this deficiency by the incorporation of all forms of feedforward and feedback connectivity between excitatory and inhibitory neuronal populations. Starting with Wilson & Cowan (1972), most modern theories functionally incorporate local $e \rightarrow e$, $e \rightarrow i$,

Figure 2. Delay embedded phase plane plots comparing EEG seizure activity recorded from rat olfactory bulb (a phylogenetically primitive form of cortex present in all mammals), top panel, and with a mesoscopic theory of olfactory bulb dynamics (bottom panel). The delay embedding is 30 ms for experimental and simulated time series of 1 s duration, with time increasing counterclockwise. Figure reproduced with permission from Freeman (1987), Copyright Springer-Verlag.

$i \rightarrow e$, and $i \rightarrow i$ connections, as illustrated in Figure 1. However, a notable exception is the influential body of work by Lopes da Silva et al. in which all the significant population neurodynamics arise out of the reciprocal interactions between excitatory and inhibitory neurons.

In the majority of theories the dynamical response of the mean soma membrane potential to synaptic activity induced by population neuronal firings is generally described using a differential formalism.

$$\dot{h}_n = -a_n h_n + \sum_{r=1}^N g_{nr}(h_n) I_{nr}, \quad (1)$$

$$\mathcal{D}_{nr} I_{nr} = S_{nr}(h_r) \quad n, r = 1 \dots N, \quad (2)$$

where N is the number of locally interacting neuronal populations and the a_n are real constants which correspond approximately to the reciprocal of the mean neuronal membrane time constant. In most theories $N = 2$. h_n is the mean soma membrane potential of the n th neuronal population, and S_{nr} defines functions that take into account the topology of neuronal population connectivity as well as the sigmoidal relationships between mean soma membrane potential and mean firing rate. $g_{nr}(h_n) I_{nr}$ represents the postsynaptic current induced in local neuronal population n by neuronal population r , whose temporal evolution is

determined by the temporal differential operator $\mathcal{D}_{nr}$. This operator takes into account bulk neurotransmitter kinetics and neuronal cable properties.

Theories of mesoscopic dynamics can generally be distinguished by the form and order of $\mathcal{D}_{nr}$, g_{nr} and S_{nr} , and N . For instance, in the original work of Wilson and Cowan, $\mathcal{D}_{nr}$ was of zero order in time, whereas in the theories of Lopes da Silva, $\mathcal{D}_{nr}$ is of first order and $g_{nr}(h_n) = \text{constant}$. More recent theories have considered $g_{nr}(h_n)$ linear in h_n and $\mathcal{D}_{nr}$ second order in time due to more detailed physiological considerations, (Liley et al., 2002). Differing forms and parametrizations of $\mathcal{D}_{nr}$, g_{nr} , and S_{nr} have been shown to give rise to a wide range of dynamics (e.g., limit cycle, chaos, and filtered noise) some of which bear strong similarities to experimental recordings (see Figure 2; see also figures in color plate section).

ELECTRON BEAM MICROWAVE DEVICES

Electron beam devices have been used in a wide variety of applications since the beginning of vacuum technology early in the 20th century. These include simple diodes and triodes, used in early radio; cathode-ray tubes, used for display in oscilloscopes, televisions, and computers; lithography; high-voltage devices used to produce X-rays; sources for electron accelerators; and the energy source for microwave devices, with applications in communications, microwave ovens, industrial processes, and electronic warfare. For the

purposes of this entry, we will limit our discussion to just one application, the production of electromagnetic energy at microwave frequencies, where nonlinear space charge effects tend to play a major role. For a wider range of applications, including the basic theory, texts are available such as Harmon (1953) and Gilmour (1994). It should be noted that solid state devices, not involving electron beams, are now often used at low power, particularly as oscillators to drive microwave electron-beam amplifiers.

Generation of microwaves with electron beams involves the interaction of a beam with electromagnetic fields across gaps of discrete cavities or synchronously with electromagnetic fields propagating on a slow wave structure. The basic physical principle is that a bunched beam interacts with the decelerating phase of an electric field to transfer energy from the beam to the field. This mechanism is the converse of the interaction in linear accelerators and synchrotrons that operate by interaction of a field in an accelerating phase with a bunched beam to transfer energy from the fields to the beam. In a device such as a traveling-wave tube (TWT) or magnetron, in which the beam interacts with a traveling wave, there is a natural bunching action as the wave develops, such that most of the beam particles are decelerated, producing the wave amplification. In a klystron, with a bunching cavity and an energy extraction cavity, the proper phase relation must be established, which is, in fact, equivalent to the synchronous condition in the TWT.

The earliest beam-type device to be extensively used for microwave generation is the magnetron, a coaxial cylindrical device with a potential between inside cathode and outside anode cylinders, and a magnetic field along the cylindrical axis. The electrons accelerated from the cathode toward the anode perform cycloidal motion due to the magnetic field with an average azimuthal drift velocity in the combined electric and magnetic fields given by $v_d = E \times B / B^2$. The anode consists of a series of microwave cavities with the operating frequency, chosen such that the cavities operate in the π -mode, that is, 180° phase shift between cavities. The fields and dimensions are chosen such that the electrons are in synchronism with the fundamental Fourier component of the fields that appear across the cavity openings. Through a complicated nonlinear process, the electrons bunch at a phase with respect to the traveling microwave field to give energy to the field, finally being collected on the anode structure with an energy considerably less than the energy eV , where V is the cathode-anode accelerating voltage. Simplified models describe some of the processes (Hutter, 1965), but most development has been experimental, assisted more recently by detailed numerical calculations (Lemke et al., 2000). The magnetron configuration described above operates naturally as an oscillator. It has high efficiency and

usually operates at high power. It was an essential element in the development of radar during World War II, which was important in winning the air war over Great Britain. The magnetron has become ubiquitous in the consumer market, as the power source in the household microwave oven. Magnetrons, despite being inexpensive and robust, have a number of unfavorable characteristics, including excess noise, narrow bandwidth, and difficulty in tuning, which limit their applications.

The klystron, which was developed roughly during the same period of time as the magnetron, is more flexible because it can operate, with small modifications, as either an amplifier or an oscillator, and versions operate over very large ranges of power and frequency. The basic configuration is two cylindrical microwave cavities with an electron beam passing through their center. The cavities have a reentrant shape such that the central hole consists of a narrow gap. The beam is velocity modulated by an alternating electric field across the first cavity gap which becomes density modulated in the second gap. At very low beam density, the electron trajectories can be taken to be kinematic, with the bunching distance related to the beam velocity and the perturbed velocity created by the gap fields. However, the usual operation is in a regime where space charge effects are fundamental to the operation. The excitation produces two waves, fast and slow space charge waves, which give a beat modulation distance $\lambda_b/4 = \pi v_o/2\omega_{pb}$, where v_o is the beam velocity and ω_{pb} is the plasma frequency of the beam. The trajectories are shown schematically in Figure 1. The beam plasma frequency is reduced from the natural electron oscillation $\omega_p = ne^2/m\epsilon_0$ due to the transverse beam dimensions. A second cavity at a

Figure 1. Distance-time diagram of a klystron indicating how velocity variations at the input grids result in density variations farther down the electron stream (after Harmon, 1953).

position $z = \lambda_b/4$ from the first cavity is excited by a maximum of the radio-frequency current in the beam. The amplifier is converted into an oscillator by either feeding back some of the signal externally from the second cavity to the first cavity or by reflecting the modulated beam, after traversing only a single cavity, to self-excite it as a reflex klystron. See a basic text such as Harmon (1953), or more detail in Hutter (1965), for mathematical analysis.

The traveling-wave tube (TWT), developed somewhat later, competes for applications with the klystron at all but the highest powers. The device transfers energy from a beam to a slow wave structure, usually a helix, by a resonant interaction in which the beam becomes naturally modulated in the presence of the wave. A linear, or small signal, analysis is sufficient to obtain the amplifying properties of the device for many low-power applications. However, as the microwave power becomes comparable to the beam power, nonlinear considerations become very important. As in the klystron, space charge is a fundamental source of nonlinearity. If significant power is extracted from the beam, the wave velocity on the circuit must be reduced along its length to maintain the coherent synchronous interaction. Due to the periodicity of slow wave structures, the propagation characteristics have operating regions for which the group velocity $v_g = d\omega/dk$ is opposite in direction to the phase velocity $v_{ph} = \omega/k$ (Brillouin, 1953). If the TWT is operated with such parameters, then wave energy is propagated backward from the direction in which the beam is moving and in which the wave amplitude, by interaction with the beam, is growing. This feedback allows the beam to self-excite the wave and therefore become an oscillator, which is called a backward wave oscillator (BWO). The operating conditions of a BWO are inherently nonlinear. In addition to the general books already mentioned, a detailed account of TWTs by one of the scientists associated with their development, is Pierce (1950). Sketches of the three basic types of devices are shown in Figures 2, 3, 4. There are many variants of these basic configurations.

Because electron beams are the power source and the active interacting medium for both klystron and TWT amplifiers and their associated oscillators, beam design is of great importance in obtaining good operating

Figure 2. Multicavity magnetron (after Hutter, 1965).

Figure 4. Helix-type traveling-wave tube (after Hutter, 1965).

characteristics. Some of the issues involved are collimation (minimizing transverse emittance), energy spread (minimizing longitudinal emittance), and high current and/or current density. The collimation is often accomplished with a uniform magnetic field along the beam axis, but radial space charge forces also lead to beam rotation. Alternatively, electric or magnetic lenses can be employed. An important consideration is to launch the beam from an accelerating region in a smooth manner; this led to the electrode shape known as the Pierce diode. An important method of confining a beam with significant space charge is to inject the beam into a uniform magnetic field from a magnetic field-free region. The proper choice of magnetic field leads to azimuthal rotation that just takes up the space charge potential, lending to smooth, uniform axial flow, called Brillouin flow. Many of the basic topics of beam dynamics and beam design are covered in Pierce (1954).

Some of the important considerations that have motivated the development of various microwave beam devices have been noise characteristics, particularly achieving low noise to amplify very low signals; frequency ranges, particularly pushing devices to increasingly high frequencies for broadband applications; tunability; and power and efficiency, particularly to obtain high power at high efficiency. For certain applications, there are also other types of constraints such as ruggedness, reliability, and weight limits, which we will not consider here. Low noise requirements have tended to favor TWTs over klystrons on the front end of receivers. Higher frequencies, used to obtain more bandwidth in communication applications, have led to miniaturization of klystrons, but other types of devices such as free electron lasers can obtain even higher frequencies for some applications (Freund & Antonsen,

1996). Some of the key issues motivating nonlinear analysis have arisen from the requirement of obtaining high efficiency at high power. Currently, the state of the art in high power is to produce IGW in a pulse of 0.1kJ. For studies of more recent analysis and developments the reader is referred to Benford & Swegle (1992) and Barker & Schamiloglu (2001).

To obtain high efficiency the majority of the electrons should be trapped in the wave field, such that they can be decelerated. This requires matching the phase space of the beam emittance to the acceptance of the wave field, usually by some additional bunching mechanisms. Some of the basic ideas are treated in Lichtenberg (1969), but each device needs detailed numerical trajectory calculations to optimize trapping. In addition to trapping, the exiting spent beam must be decelerated to retrieve the excess energy (a depressed collector). Reducing the collector voltage is limited by the requirement that the average beam energy of the exiting beam must be greater than its energy spread so as not to turn electrons around. This condition requires knowledge of the nonlinear characteristics of the longitudinal phase space emittance.

ELLIPTIC FUNCTIONS

Elliptic functions were first introduced as inverses of elliptic integrals, so called because the integral for the arclength of the ellipse studied by John Wallis in the 17th century (Stillwell, 1989) was the first such example. By the end of the 18th century, in particular after the work of Leonhard Euler, Joseph-Louis Lagrange, and Adrien-Marie Legendre, mathematicians had realized

that integrals of the form $\int dx/\sqrt{P(x)}$, where $P(x)$ is a cubic or quartic polynomial, could not be expressed in terms of elementary functions (or their inverses). Many elliptic integrals arise naturally in the solutions of problems in mechanics (Lawden, 1989). For example, the solution of the simple pendulum equation

$$\dot{\theta} + \omega^2 \sin \theta = 0$$

can be obtained using conservation of energy $\frac{1}{2}(\dot{\theta})^2 - \omega^2 \cos \theta = E$, $E > -\omega^2$, to arrive at the inversion problem for the integral

$$t - t_0 = \int_0^\theta \frac{d\theta}{\sqrt{2E + \omega^2 - \omega^2 \sin^2(\theta/2)}} d\theta.$$

Substituting $z = \sin(\theta/2)$ and defining $k^2 = \omega^2/(E + \omega^2) \in (0, 1)$, one arrives at the expression

$$K(z; k) = \int_0^z \frac{dz}{\sqrt{1-z^2}\sqrt{1-k^2z^2}} = \frac{\omega}{k}(t - t_0). \quad (1)$$

In the late 19th century, Niels Henrik Abel, Carl Jacobi, and Carl Friedrich Gauss observed the similarity between $K(z; k)$ and the integral defining the transcendental function $\arcsin z$ as

$$\arcsin z = \int_0^z \frac{dz}{\sqrt{1-z^2}}$$

(which is indeed the limiting case of (1) as $k \rightarrow 0$, giving the solution for the small amplitude oscillations of the pendulum), and introduced the *Jacobi elliptic sine function* $\text{sn}(z; k)$ as the inverse of $K(z; k)$

$$z = K(\text{sn}(z; k); k).$$

While the circular (trigonometric) functions $\sin z$, $\cos z$, $\tan z$, etc., are singly periodic functions of the complex variable z , satisfying $f(z + 2\pi) = f(z)$, elliptic functions can be characterized as the doubly periodic functions, which only possess pole singularities. Elliptic functions satisfy

$$f(z + 2\omega_1) = f(z), \quad f(z + 2\omega_2) = f(z),$$

where ω_1 and ω_2 (the *periods* of f) are complex numbers such that ω_1/ω_2 is not purely real. The region of the complex plane with vertices $\{0, 2\omega_1, 2\omega_2, 2\omega_1 + 2\omega_2\}$ is called the *fundamental period parallelogram* (see Figure 1).

The simplest elliptic functions are those with two poles: the *Jacobi elliptic functions*, with two simple poles of opposite residues, and the *Weierstrass elliptic functions*, with a single double pole with zero residue, all others can be constructed from these.

Jacobi Elliptic Functions

The three most common Jacobi elliptic functions are $\text{sn}(z; k)$, introduced earlier, and the associated

Figure 1. The period lattice of an elliptic function.

Figure 2. Graphs of $\text{sn}(x; k)$ (solid line) and $\text{cn}(x; k)$ (dashed line), for real x , $k = 0.5$.

$\text{cn}(z; k) = \sqrt{1 - \text{sn}^2(z; k)}$ (a generalization of the cosine function) and $\text{dn}(z; k) = \sqrt{1 - k^2 \text{sn}^2(z; k)}$. Some of their main properties, analogues of the properties of trigonometric functions, are listed below; their proofs are elementary (Whittaker & Watson, 1943) (see Figure 2):

Symmetry:

$$\begin{aligned} \text{sn}(-u) &= -\text{sn } u, & \text{cn}(-u) &= \text{cn } u, \\ \text{dn}(-u) &= \text{dn } u. \end{aligned}$$

Derivatives:

$$\begin{aligned} \frac{d}{du} \text{sn } u &= \text{cn } u \text{ dn } u, & \frac{d}{du} \text{cn } u &= -\text{sn } u \text{ dn } u, \\ \frac{d}{du} \text{dn } u &= -k^2 \text{sn } u \text{ cn } u. \end{aligned}$$

Addition formulas: For example,

$$\text{sn}(u + v) = \frac{\text{sn } u \text{ cn } v \text{ dn } v + \text{sn } v \text{ cn } u \text{ dn } u}{1 - k^2 \text{sn}^2 u \text{sn}^2 v}.$$

Periods: Define the *complete elliptic integral*

$$K = \int_0^1 \frac{dz}{\sqrt{(1-z^2)(1-k^2z^2)}},$$

the *complementary modulus* k' such that $k^2 + k'^2 = 1$, and the constant $K' = K(1; k')$. Then, for example,

$$\text{sn}(u + 4K) = \text{sn } u, \quad \text{sn}(u + 2iK') = \text{sn } u.$$

Figure 3. The doubly periodic function $\operatorname{sn}(z; k)$: graph of $\operatorname{Re}[\operatorname{sn}(z; 0.3)]$.

Poles: For example, $\operatorname{sn}(z; k)$ is analytic except at points congruent to iK' and $2K + iK'$ (mod $2K, 2iK'$), which are simple poles.

Weierstrass Elliptic Functions

This class of elliptic functions was introduced by Weierstrass by means of infinite partial-fraction and product expansions, rather than as inversions of elliptic integrals. Indeed, such construction exists for all elliptic functions. Given $\omega_1, \omega_3 \in \mathbb{C}$, $\omega_2 = \omega_1 + \omega_3$, we define the most famous of Weierstrass' elliptic functions, the $\wp$ -function, on the period lattice $\{m2\omega_1 + n2\omega_3 \mid m, n \in \mathbb{Z}\}$:

$$\wp(z) = \frac{1}{z^2} + \sum_{(m,n) \neq (0,0)} \left\{ \frac{1}{(z - (m2\omega_1 + n2\omega_3))^2} - \frac{1}{(m2\omega_1 + n2\omega_3)^2} \right\}. \tag{2}$$

$\wp(z)$ is a meromorphic function with double poles at each point of the period lattice and satisfies the following differential equation:

$$\begin{aligned} [\wp'(z)]^2 &= 4[\wp(z)]^3 - g_2[\wp(z)] - g_3 \\ &= 4(\wp(z) - e_1)(\wp(z) - e_2)(\wp(z) - e_3), \end{aligned} \tag{3}$$

where $e_i = \wp(\omega_i)$.

Among applications of the Weierstrass $\wp$ -function is the profile of a wave traveling in water (see, e.g., Walker, 1996), as described by the Korteweg–de Vries (KdV) equation

$$u_t + u_x + 12uu_x + u_{xxx} = 0. \tag{4}$$

Seek a traveling-wave solution by setting $u(x, t) = f(x - ct)$, for some constant speed c . Then f satisfies the ordinary differential equation $(1 - c)f' + 12ff' - + f''' = 0$ which, after twice integrating, leads to

$$(f')^2 = 4f^3 - (1 - c)f^2 + Af + B,$$

Figure 4. The profile of the cnoidal wave solution of the KdV equation, $A = 4, k = 0.3$.

A, B constants of integration. By comparison with (3), the form of f must be $f(s) = \alpha \wp(\beta s) + \gamma$, for suitable constants α, β, γ . Since the Weierstrass $\wp$ -function can be shown to be related to the square of Jacobi elliptic functions (Whittaker & Watson, 1943), this leads to the notable *cnoidal wave* solution of KdV (see Figure 4):

$$\begin{aligned} u(x, t) &= A \operatorname{cn}^2 \left(\frac{\sqrt{A}}{k} (x - ct); k \right), \\ c &= 1 + 4A \frac{2k^2 - 1}{k^2}. \end{aligned}$$

Finally, we briefly mention hyperelliptic functions (or abelian functions), as inverses of integrals of rational functions $R(z, \sqrt{P(z)})$, with $P(z)$ a quintic or higher-degree polynomial (Baker, 1995). For example, the equations for the Kovalevsky top were shown by Sophia Kovalevsky to be integrable in terms of hyperelliptic functions (Whittaker, 1960).

EMBEDDING METHODS

The modeling of a deterministic dynamical system relies on the concept of a phase space, which is a theoretical representation of the totality of possible system states. In general, a system state consists of information of positions and velocities needed to specify all future system states. For a system that has a mathematical model, the phase space is known from the equations of motion.

For experimental and natural chaotic dynamical systems, the full state space is unknown. Embedding methods have been developed as a means to reconstruct the phase space and develop new predictive models. One or more signals from the system must be observed as a function of time. The time series are then used to build a proxy of the observed states.

Mathematical theorems show how the observed time series can be used. A famous theorem of Hassler Whitney from the 1930s holds that a generic map from an n -manifold to $2n + 1$ -dimensional Euclidean space is an embedding. In particular, the image of the n -manifold is completely unfolded in the larger space because $2n + 1$ signal traces measured from a system can be considered as a map from the set of states to $2n + 1$ -dimensional space. Whitney's theorem implies that each state can be identified uniquely by a vector of $2n + 1$ measurements, thereby reconstructing the phase space.

The contribution of Floris Takens (1981) was to show that the same goal could be reached with a single measured quantity. He proved that instead of $2n + 1$ generic signals, the time-delayed versions $[y(t), y(t - \tau), y(t - 2\tau), \dots, y(t - 2n\tau)]$ of one generic signal would suffice to embed the n -dimensional manifold. There are some technical assumptions that must be satisfied, restricting the number of low-period orbits with respect to the time-delay τ and repeated eigenvalues of the periodic orbits. This result was roughly contemporaneous with similar theoretical results by D. Aeyels and a more empirical account by Packard et al. (1980).

The idea of using time delayed coordinates to represent a system state is reminiscent of the theory of ordinary differential equations, where existence theorems say that a unique solution exists for each $[y(t), \dot{y}(t), \ddot{y}(t), \dots]$. For example, in Newtonian many-body dynamics, current knowledge of the position and momentum of each body suffices to uniquely determine the future dynamics. The time derivatives can be approximated by delay-coordinate terms as

$$\left[y(t), \frac{y(t) - y(t - \tau)}{\tau}, \frac{y(t) - 2y(t - \tau) + y(t - 2\tau)}{\tau^2}, \dots \right].$$

The emergence of chaos and fractal geometry in physical systems motivated a reassessment of the original theory, which applies to smooth manifold attractors. It was shown (Sauer et al., 1991) that an attractor of (possibly fractional) box-counting dimension d can always be reconstructed with m generic observations, or with m time-delayed versions of one generic observation, where m is any integer greater than $2d$.

Embedding ideas were later extended beyond autonomous systems with continuously measured time series. A version was designed for excitable media, where information may be transmitted by spiking events, extending usage to possible neuroscience applications. An embedding theorem for skew systems by J. Stark explores extensions of the methodology when one part of a system is driving another.

Although the theory implies that an arbitrary time delay is sufficient to reconstruct the attractor, efficiency with a limited amount of data is enhanced by particular choices of the time delay τ . Methods for choosing an appropriate time delay have centered on measures of linear autocorrelation and mutual information (Fraser & Swinney, 1986). Further, in the absence of knowledge of the phase space dimension n , a choice of the number of embedding dimensions m must also be made. A number of ad hoc methods have been proposed that try to estimate whether the image has been fully unfolded by a given m -dimensional map.

The success of embedding in practice depends heavily on the specifics of the application. In particular, the hypothesis of a generic observation function creating the time series is often problematic. A mathematically generic observation monitors by definition all degrees of freedom of the system. The extent to which this is true affects the faithfulness of the reconstruction. If there is only a weak connection from some degrees of freedom to the observation function, the data requirements for a satisfactory reconstruction may be prohibitive in practice. Other factors that limit success are difference in time scales between different parts of the system, as well as system and observational noise.

Applications of embedding time-series data (Ott et al., 1994; Kantz & Schreiber, 1997) have been extensive since Takens's theorem was published. Many techniques of system characterization and identification were made possible, including determination of periodic orbits and symbolic dynamics, as well as approximation of attractor dimensions and Lyapunov exponents of chaotic dynamics. In addition, researchers have focused on methods of time series prediction and nonlinear filtering for noise reduction, the use of chaotic signals for communication, and the control of chaotic systems.

EMERGENCE

Like many commonly used words, the term *emergence* has several meanings. In its weakest sense, a metaphor is provided by Michelangelo Buonarroti's famous sculptures entitled *The Prisoners*, which show human figures struggling to free themselves from their lithic confines, suggesting the artist's view of the creative process.

In simplest terms, there is little mystery here; the sculptor merely removes the unnecessary marble to expose the finished work, as Michelangelo himself is said to have pointed out. Thus, his prisoners are emerging only in an elementary sense which philosopher Robert Van Gulick calls "specific value emergence" and defines as follows (Van Gulick, 2001):

SPECIFIC VALUE EMERGENCE: The whole and its parts have features of the *same kind*, but have different *specific subtypes* or *values* of that kind. For example, a bronze statue has a given mass as does each of the molecular parts of which it is composed, but the mass of the whole is different in value from that of any of its material parts.

Moving beyond this limited sense, Van Gulick defines various degrees of "modest emergence" in these terms.

MODEST EMERGENCE: The whole has features that are *different in kind* from those of its parts (or alternatively that *could* be had by its parts). For example, a piece of cloth might be purple in hue even though none of the molecules that make up its surface could be said to be purple. Or a mouse might be alive even if none of its parts (or at least none of its subcellular parts) were alive.

Modest emergence thus arises in a spectrum of different ways depending upon the degree of difference between a phenomenon and the base out of which it emerges, with the coherent structures of nonlinear science providing many examples (Scott, 2003).

Among the more modest types of emergence, one would include solitons of the Korteweg–de Vries

(KdV) equation, which emerge out of a nonlinear partial differential equation (PDE) in response to certain initial conditions. Although KdV solitons are independent dynamic entities, their speeds and shapes are determined via the inverse scattering transform (IST) method from the initial conditions applied to the system. Somewhat less modest would be the various solitary wave solutions of Hamiltonian (energy conserving) systems for which IST formulations are not currently known and may not exist, precluding the prediction of solitary wave speeds from initial conditions.

Further decreasing modesty (increasing robustness) of emergence leads to the nerve impulse, which has several model PDEs (Hodgkin–Huxley, FitzHugh–Nagumo, etc.) in addition to those many physiological manifestations (the action potentials of the brain) which compose our mental activity (Scott, 2002). While propagating on a uniform system with constant speed and shape, a nerve impulse differs fundamentally from solitary waves of Hamiltonian systems for the following reason: a nerve impulse (like the flame of a candle) does not conserve energy. The nonlinear dynamics of a nerve impulse involves a balance between the release and dissipation of energy, so the process is open and thus does not have a Hamiltonian formulation. This, in turn, implies that the dynamic behavior of a nerve impulse changes greatly upon reversal of the direction of time, whereas the qualitative behavior of a Hamiltonian system is insensitive to time reversal.

Under this distinction, we can gauge the relative modesty of several other types of emergence that arise in the realms of nonlinear science. Vortex solutions of viscosity-free fluids (superfluids, for example) would be more modestly emergent than those of (more or less) viscous fluids, in which dissipative processes cause the dynamics to (more or less) rapidly forget the information received from the initial conditions. As residents of Tornado Alley in the U.S. midlands know well, tornados are famously ill-behaved, detached from their initial conditions and moving quite wildly in response to local variations of pressure, humidity, temperature, and so on.

A deeper meaning of Michelangelo's metaphor suggests the emergence of living organisms from the oily brine of the Hadean oceans some three thousand million years ago. Life is even less modestly (more robustly) emergent, with the "arrow of time" clearly constraining us all and playing a key role in the unpredictable drama of biological evolution (Gould, 1989). In other words, the emergence of life is far more intricate than the emergence of John Scott Russell's soliton from the prow of his test vessel on the Union Canal.

Yet more robust (less immodest) than the emergence of life is the phenomenon of human consciousness, which philosophers have struggled for centuries to

understand and many find qualitatively different from its material substrate. To include the qualitative aspects of emergence at this far end of the scale, Van Gulick introduces the following definition.

RADICAL EMERGENCE: The whole has features that are both different in kind from those had by its parts, and of a kind whose nature and existence is not necessitated by the features of its parts, their mode of combination and the law-like regularities governing the features of its parts.

Whether human consciousness offers an example of radical emergence is currently controversial among cognitive scientists, neuroscientists, psychologists, cultural anthropologists, philosophers, and others interested in the nature of mind. On the one hand, reductive materialists assert that all of reality must “in principle” reduce to a physical basis (Kim, 1999), whereas substance dualists claim that the human mind differs ontologically (in its nature) from physical reality (Chalmers, 1996). Situated between these two positions, property dualists suggest that the human mind may radically emerge from intricate interactions among the various nonlinear dynamic levels of body, brain, and culture (Scott, 1995; Van Gulick, 2001).

ENERGY ANALYSIS

In time-reversible Hamiltonian systems, the total energy of the system is constant in time. A local change of the energy density W at a point x in time t is balanced

by the energy flux S from/to the point x according to the energy balance equation:

$$\frac{\partial W}{\partial t} + \frac{\partial S}{\partial x} = 0.$$

In irreversible (active and/or dissipative) systems, the total energy changes in time due to the energy sinks/sources of density ρ are given by the extended the extended energy balance equation:

$$\frac{\partial W}{\partial t} + \frac{\partial S}{\partial x} = -\rho.$$

In mathematical physics, energy balance is used for analysis of well-posedness of partial differential equations. Solutions of well-posed differential equations remain bounded in a suitable function space, starting with a bounded initial data (Strauss, 1992). For illustration, we consider the energy balance for the heat equation $u_t = u_{xx}$ that takes the form

$$\frac{\partial}{\partial t} (u^2) - 2 \frac{\partial}{\partial x} (uu_x) = -2 (u_x)^2.$$

Suppose the initial data $u(x, 0)$ belong to space of real-valued $L^2(\mathcal{R})$ functions such that the initial energy is bounded: $E(0) = \int_{-\infty}^{\infty} u^2(x, 0) dx < \infty$. The energy $E(t)$ decreases at later times such that $0 \leq E(t) = \int_{-\infty}^{\infty} u^2(x, t) dx \leq E(0)$. These simple estimates of energy analysis immediately imply the following properties of the heat equation:

- (i) The zero solution $u(x, t) = 0$ is unique.
- (ii) A general solution $u(x, t)$ is asymptotically stable in space of $L^2(\mathcal{R})$ functions.
- (iii) A general solution $u(x, t)$ decays uniformly to zero in the L^2 -norm sense: $\lim_{t \rightarrow \infty} \|u(\cdot, t)\|_{L^2(\mathcal{R})} = 0$.

A real-valued energy can be introduced for complex functions, for example, in the Schrödinger equation $iu_t = u_{xx}$, where the energy balance takes the form

$$\frac{\partial}{\partial t} |u|^2 + i \frac{\partial}{\partial x} (\bar{u}u_x - u\bar{u}_x) = 0.$$

The Schrödinger equation is reversible, and the total energy is constant in time such that $0 \leq E(t) = \int_{-\infty}^{\infty} |u|^2(x, t) dx = E(0)$. As a result, the solution is well-posed in the space of complex-valued $L^2(\mathcal{R})$ functions with the following properties:

- (i) The zero solution $u(x, t) = 0$ is unique.
- (ii) A general solution $u(x, t)$ is neutrally stable in the L^2 -norm sense.

Partial differential equations can be well-posed in energy space, which is different from the space of square integrable functions. For the wave equation $u_{tt} = c^2 u_{xx}$, two balance equations take the form

$$\frac{\partial}{\partial t} (u_t^2 + c^2 u_x^2) - 2c^2 \frac{\partial}{\partial x} (u_t u_x) = 0$$

and

$$\frac{\partial}{\partial t}(u_t u_x) - \frac{1}{2} \frac{\partial}{\partial x}(u_t^2 + c^2 u_x^2) = 0.$$

The first equation prescribes the positive-definite quantity, $E(t) = \int_{-\infty}^{\infty} (u_t^2 + c^2 u_x^2) dx$, which defines the energy space $H^1(\mathcal{R})$ for solutions of the wave equation, such that $0 \leq E(t) = E(0)$. The second equation prescribes the sign-indefinite quantity, $P(t) = \int_{-\infty}^{\infty} u_t u_x dx$, referred to as the momentum, such that $\dot{P}(t) = P(0)$.

In modeling of various physical phenomena, momentum balance equations are useful for analysis of integral properties of solutions of underlying equations at infinite or finite intervals. For instance, adiabatic dynamics of localized pulses, envelope wave packets, and radiative wave trains can be studied with the momentum balance equations, when a solitary wave changes under the action of external perturbations, variations of physical parameters, internal instabilities, various resonances, and interactions with other wave structures (Kivshar & Malomed, 1989). In the simplest version of the soliton perturbation theory, effects of external perturbations to a physical system are captured by slow variations of soliton parameters. The dynamical rate of change of soliton parameters is found by substituting the soliton solutions in the momentum balance equations. For illustration, we consider the perturbed sine-Gordon equation with dissipative and external harmonic forces:

$$u_{tt} - u_{xx} + \sin u = \varepsilon R(u) \\ = \varepsilon [-\alpha u_t + \Gamma \sin(\omega t)(1 - \cos u)],$$

where $\varepsilon \ll 1$, α is a damping parameter and Γ is the amplitude of the external force such that $\omega < 1$ (no resonance occurs). With the account of the perturbation, the balance equation for momentum is

$$\frac{\partial}{\partial t}(u_t u_x) - \frac{1}{2} \frac{\partial}{\partial x}(u_t^2 + u_x^2 + 2 \cos u) = \varepsilon R(u) u_x.$$

As a result, the rate of change of momentum $P(t) = \int_{-\infty}^{\infty} u_t u_x dx$ is given by

$$\frac{dP}{dt} = \varepsilon \int_{-\infty}^{\infty} u_x R[u] dx.$$

provided that $\lim_{|x| \rightarrow \infty} (u_t^2 + u_x^2) = 0$ and $\lim_{x \rightarrow \infty} \cos u = \lim_{x \rightarrow -\infty} \cos u = 1$. The unperturbed sine-Gordon equation at $\varepsilon = 0$ has the kink solution:

$$u_k(x, t) = 4 \arctan \left(\exp \left(\frac{x - vt - x_0}{\sqrt{1 - v^2}} \right) \right),$$

where $|v| < 1$ is the kink's velocity and x_0 is its position. The momentum of the unperturbed kink is a function of its velocity: $P_k(v) = -8v/\sqrt{1 - v^2}$. The kink solution satisfies the aforementioned vanishing conditions at

infinity. Assuming that the velocity of the kink $v = v(t)$ changes due to the external perturbation, we use the momentum balance equation and find a particle-like equation of motion for the kink's adiabatic dynamics:

$$\frac{dP_k}{dt} + \varepsilon \alpha P_k = 2\pi \varepsilon \Gamma \sin(\omega t).$$

The equation has a simple solution:

$$P_k(t) = C e^{-\varepsilon \alpha t} \\ - \frac{2\pi \varepsilon \omega \Gamma}{\omega^2 + \varepsilon^2 \alpha^2} \cos \omega t \\ + \frac{2\pi \varepsilon^2 \alpha \Gamma}{\omega^2 + \varepsilon^2 \alpha^2} \sin \omega t,$$

where C is found from initial condition: $P_k(0) = P_0$.

Adiabatic dynamics of kinks and solitary waves often generate a strong radiation field that takes away part of momentum of the localized solution. The radiation field can be taken into account from other balance equations, such as the mass balance. Radiative effects usually occur in the second order of the perturbation theory, leading to radiative decay of solitary waves or their perturbations (Pelinovsky & Grimshaw, 1996). For illustration, we consider dynamics of solitary waves in the critical KdV equation:

$$u_t + 15u^4 u_x + u_{xxx} = 0.$$

The balance equations for mass and momentum of a nonlinear field are:

$$\frac{\partial}{\partial t}(u) + \frac{\partial}{\partial x}(3u^5 + u_{xx}) = 0$$

and

$$\frac{\partial}{\partial t}(u^2) + \frac{\partial}{\partial x}(5u^6 + 2uu_{xx} - u_x^2) = 0.$$

Solitary waves are given by special solutions of the critical KdV equation:

$$u_s(x, t) = [\sqrt{v} \operatorname{sech}(2\sqrt{v}(x - vt - x_0))]^{1/2}.$$

Solitary waves may change adiabatically due to internal perturbation of the initial data, such that v becomes a function of t . The radiation field is generated behind the solitary wave due to the uni-directional property of the dispersion relation for the linear KdV equation: $u_t + u_{xxx} = 0$. The radiation field can be found from the mass balance equation

$$\lim_{x \rightarrow -\infty} u(x, t) = -\frac{1}{v} \frac{dM_s}{dt},$$

where $M_s(v) = \int_{-\infty}^{\infty} u_s(x, t) dx = M_0/v^{1/4}$ and M_0 is constant. The momentum balance equation leads to a closed particle-like equation of motion for the solitary

wave's adiabatic dynamics:

$$\begin{aligned} \frac{d}{dt} \left[\left(\frac{dM_s}{dv} \right)^2 \frac{dv}{dt} \right] &= -v \left[\lim_{x \rightarrow -\infty} u(x, t) \right]^2 \\ &= -\frac{1}{v} \left(\frac{dM_s}{dv} \right)^2 \left(\frac{dv}{dt} \right)^2. \end{aligned}$$

The dynamical equation has a unique solution:

$$v(t) = v_0 \left(\frac{t_0}{t_0 - t} \right)^2,$$

where v_0 and t_0 are constants. The exact solution defines the scaling law for self-similar blowup in the critical KdV equation. The blowup rate is modified due to generation of the radiation field, which makes the balance between the left- and right-hand sides of the momentum balance equation. To summarize, the balance equations for energy, momentum, and mass can be used for both qualitative and quantitative estimates of the interaction between localized and radiative components of the nonlinear wave in solutions of nonlinear wave equations.

ENTROPY

Entropy is a quantity characterizing disorder, or randomness. This conclusion is the result of successive

advances since the pioneering works by Sadi Carnot on the fundamentals of steam engines in 1824 and by Rudolf Clausius, who, between 1851 and 1865, developed the concept of entropy (from $\tau\rho\sigma\pi\eta$ meaning “transformation” in Greek) as a thermodynamic state variable. Called S , this quantity varies as $dS = dQ/T$ in an equilibrium system at temperature T exchanging a quantity dQ of heat and no matter reversibly with its environment.

Thereafter, Ludwig Boltzmann (1896/1898), Max Planck (1901), Josiah Willard Gibbs (1902), and others discovered the statistical meaning of entropy. Boltzmann and Gibbs introduced the concepts of probability and statistical ensemble in the context of mechanics. If P_α is the probability (satisfying $0 \leq P_\alpha \leq 1$ and $\sum_\alpha P_\alpha = 1$) that the system is found in the microstate α specified by a set of observables such as energy and linear or angular momenta, the thermodynamic entropy is given by

$$S = -k_B \sum_\alpha P_\alpha \ln P_\alpha, \quad (1)$$

where $k_B = 1.38065 \cdot 10^{-23} \text{ J K}^{-1}$ is the so-called Boltzmann constant, although it was originally introduced by Planck (Sommerfeld, 1956).

The entropy S measures the disorder in a statistical ensemble composed of a very large number, $\mathcal{N}$, of copies of the system. Each copy is observed in a microstate α occurring with the probability P_α . The microstates of all the $\mathcal{N}$ copies form a random list $\{\alpha_1, \alpha_2, \dots, \alpha_{\mathcal{N}}\}$. Typically, $\mathcal{N}_\alpha = \mathcal{N} P_\alpha$ copies are found in the microstate α , and $\sum_\alpha \mathcal{N}_\alpha = \mathcal{N}$. The copies being statistically independent, the total number of possible lists of the microstates of the ensemble is thus equal to

$$W = \frac{\mathcal{N}!}{\prod_\alpha \mathcal{N}_\alpha!}, \quad (2)$$

where $\mathcal{N}! = \mathcal{N} \times (\mathcal{N} - 1) \times \dots \times 3 \times 2$ denotes the factorial of the integer $\mathcal{N}$. In the limit $\mathcal{N} \rightarrow \infty$, according to Stirling's formula $\mathcal{N}! \simeq (\mathcal{N}/e)^{\mathcal{N}}$, where $e = 2.718\dots$ denotes the Napierian base, entropy (1) is given in terms of the logarithm of the number W of possible lists (originally called complexions by Boltzmann):

$$S \simeq \frac{k_B}{\mathcal{N}} \ln W. \quad (3)$$

If the system is perfectly ordered, all the copies in the ensemble would be in the same microstate, and there would be a single possible complexion $W = 1$ so that the entropy would vanish ($S = 0$). In contrast, if the system were completely disordered with A equiprobable microstates α , the entropy would take the maximum value $S = k_B \ln A$. For partial disorder, the entropy takes an intermediate value.

In spatially extended homogeneous systems, the thermodynamic entropy is an extensive quantity. If the

system is covered by $\mathcal{N}$ disjoint windows of observations of volume V , the microstates $\{\alpha_1, \alpha_2, \dots, \alpha_{\mathcal{N}}\}$ in the $\mathcal{N}$ windows form one among W possible lists (2). If the volume V of the observation window is large enough, the thermodynamic entropy is again given by Equation (3). In this case, the entropy per unit volume obtained by dividing the entropy S by the volume V is a measure of spatial disorder.

Entropy can also be interpreted as a quantity of information required to specify the microstate of the system. Indeed, the recording of the random microstates $\{\alpha_1, \alpha_2, \dots, \alpha_{\mathcal{N}}\}$ of the statistical ensemble requires one to allocate at least $I = \log_2 W$ bits of information in the memory of a computer. This number of bits is related to the entropy (1) by $I \simeq \mathcal{N}S/(k_B \ln 2)$. Such connections between entropy and information have been developed since the works by Leo Szilard in 1929 and Léon Brillouin around 1951.

Equation (1) for the entropy is very general. It applies not only to equilibrium but also to out-of-equilibrium systems provided the states α are understood as coarse-grained states. In a classical system of N particles, the coarse-grained states α should correspond to cells of volume h^{3N} in the phase space of the positions and momenta of the particles, where $h = 6.626 \cdot 10^{-34}$ Js is Planck's constant of quantum mechanics.

In 1902, Gibbs suggested that the second law of thermodynamics is a consequence of a dynamics having the mixing property according to which the statistical averages of observables or the coarse-grained probabilities P_α converge to their equilibrium values. Not all systems are mixing, but for those that are, entropy (1) converges toward its equilibrium value. In mixing systems, the statistical correlations in the initial probability distribution tend to disappear on finer and finer scales in phase space and are shared among more and more particles during a causal time evolution. The approach to the thermodynamic equilibrium may thus be described in terms of asymptotic expansions of the probability distributions in the long-time limits $t \rightarrow \pm\infty$. Both limits are not equivalent because, in the limit $t \rightarrow +\infty$, the probability distributions remain smooth in the unstable phase-space directions but become singular in the stable ones and vice versa in the other limit $t \rightarrow -\infty$, which may appear as an irreversibility or time arrow in the long-time description. The irreversibility in the increase of the entropy is thus closely related to the problems of identifying all the degrees of freedom guaranteeing the causality of the time evolution and of reconstructing the initial conditions, which is of great importance for the understanding of historical processes such as biological and cosmological evolution.

During recent decades, it has been shown that the increase of entropy does not preclude the formation of structures in equilibrium or non-equilibrium systems, nor in self-gravitating systems. At equilibrium, the

homogeneity of pressure, temperature, and chemical potentials does not prevent inhomogeneities in the densities as is the case in crystals, in vortex states of quantum superfluids, and in mesomorphic phases of colloidal systems where equilibrium self-assembly occurs. Besides, open non-equilibrium systems can remove entropy to their environment, leading to far-from-equilibrium self-organization into spatial structures such as Turing patterns, self-sustained oscillations in such systems as chemical clocks, or complex processes such as biological morphogenesis.

While the entropy per unit volume characterizes spatial disorder at a given time, a concept of entropy per unit time was introduced in 1949 by Claude Shannon in development of his information theory, as a measure of temporal disorder in random or stochastic processes. It is defined in the same way as standard entropy but replacing space by time. In 1959, Andrei N. Kolmogorov and Yakov G. Sinai applied Shannon's idea to deterministic dynamical systems with an invariant probability measure, and they defined a metric entropy per unit time in analogy with Equation (1), considering the states α as the sequences $\omega_1\omega_2\dots\omega_n$ of the phase space cells ω_j successively visited at time intervals Δt by the trajectories during the time evolution of the system. In order to get rid of the arbitrariness of the coarse-grained cells ω_j , Kolmogorov and Sinai considered the supremum (least upper bound) of the entropy per unit time with respect to all possible partitions $\mathcal{P}$ of the phase space into cells ω_j , defining

$$h_{KS} = \sup_{\mathcal{P}} \lim_{n \rightarrow \infty} -\frac{1}{n\Delta t} \times \sum_{\omega_1\omega_2\dots\omega_n} P_{\omega_1\omega_2\dots\omega_n} \ln P_{\omega_1\omega_2\dots\omega_n}, \quad (4)$$

where the probability P is evaluated with the given invariant measure (Cornfeld et al., 1982).

In isolated chaotic dynamical systems, the temporal disorder of the trajectories finds its origin in the sensitivity to initial conditions because the Kolmogorov-Sinai entropy per unit time is equal to the sum of positive Lyapunov exponents λ_i , $h_{KS} = \sum_{\lambda_i > 0} \lambda_i$, as proved by Yakov B. Pesin in 1977 (Eckmann & Ruelle, 1985). We notice that the entropy per unit time h_{KS} differs from the irreversible entropy production defined by the time derivative of the standard thermodynamic entropy S in an isolated system. Indeed, the entropy per unit time may take a positive value for a system of particles already at thermodynamic equilibrium where entropy production vanishes. In spatially extended chaotic systems, the spatiotemporal disorder can be characterized by a further concept of entropy per unit time and unit volume.

A so-called topological entropy has also been introduced as the rate of proliferation of cells in

successive partitions iteratively refined by the dynamics (Eckmann & Ruelle, 1985). In finite chaotic systems, the topological entropy is the rate of proliferation of periodic orbits as a function of their period. The topological entropy is not smaller than the Kolmogorov–Sinai entropy: $h_{\text{top}} \geq h_{\text{KS}}$.

EPHAPTIC COUPLING

Neurons communicate with each other by different means. The most investigated of these is synaptic transmission, which can be either chemical or electrical. Chemical synapses transmit neural signals from presynaptic to postsynaptic membranes via neurotransmitters and are widely found in vertebrate neurons, while electrical synapses correspond to an electronic coupling through specialized gap junctions and are more common in invertebrates (Jefferys, 1995). Therefore, both transmission processes need a specialized anatomical structure to create points of contact between neurons but there are other possibilities.

Since the work of Elwald Hering in 1882, it has been known that electrical communication can also occur between neurons when neuronal membranes are closely apposed but not contiguous (Scott, 2002). Called ephaptic coupling by Angeliue Arvanitaki (who defined the term *ephapse* as “... the locus of contact or close vicinity of the active functional surfaces, whether this contact be experimental or brought by natural means”), this process relies on current spread through the extracellular space, which may influence the membrane dynamics of a second fiber (Arvanitaki, 1942). Early experimental evidence of ephaptic interactions was also provided by Bernhard Katz and Otto Schmitt on a pair of naturally adjacent unmyelinated fibers from the limb nerve of a crab (Katz & Schmitt, 1940). They showed that an impulse traveling on one fiber changes the excitability of the other fiber. Furthermore, impulses on adjacent fibers with similar speed and launched at about the same time become synchronized.

In the 1970s, Markin proposed a theoretical description of ephaptic coupling between two parallel unmyelinated fibers based on the assumption that they share an external series resistance per unit length proportional to the ionic resistivity of the extracellular medium (Markin, 1970). Using a piecewise constant function for the transmembrane ionic current, yielding to a leading-edge analysis, Markin concluded that under normal physiological conditions, ephaptic coupling does not allow transmission of an impulse from a fiber to an adjacent one, as verified in numerous experiments. Nevertheless, he also suggested that a synchronization of two impulses is to be expected with a longitudinal distance δ equal to zero.

A recent leading-edge analysis (Scott, 2002) considered a more appropriate representation of the ionic current (sodium ions), the resulting system corresponding to the Zeldovich–Frank–Kamenetsky (ZF) equation. In the case of a small ephaptic coupling, a perturbation theory showed that $\delta = 0$ corresponds to a stable locking of pairs of impulses if the threshold parameter a of the membrane is above a critical value, otherwise stability occurs with δ increasing when a decreases.

Other possibilities of synchronization have been found when studying the influence of complete impulses including a leading edge and a recovery part. Based on the FitzHugh–Nagumo model, studies have shown that two other locking distances δ are also stable and separated by two unstable ones (Scott, 2002; Eilbeck et al., 1981). Recently, it has also been shown that ephaptic coupling influences the speed of conduction of synchronized impulses, the speed decreasing when the coupling increases (Binczak et al., 2001).

In mammals, motor or sensory nerves are often organized in fiber bundles. These fibers are myelinated, and the active nodes of the membrane are separated

Figure 1. Sketch of two adjacent and parallel myelinated nerve fibers.

by a myelin sheath, which acts as an insulator. Thus, ephaptic coupling may be influenced by the alignment of the active nodes between two adjacent fibers (Binczak et al., 2001), as illustrated in Figure 1 where A is an alignment parameter.

Using a ZF description for the ionic current, a leading-edge analysis suggests that synchronization of impulses occurs whatever the alignment A . Nevertheless, an alignment of the nodes ($A=1$) leads to a stronger synchronization while staggered nodes ($A=\frac{1}{2}$) allow a broader impulse coupling. Furthermore, when impulses are synchronized, an alignment of adjacent nodes reduces the critical longitudinal internodal distance at which propagation fails. Staggered nodes, on the other hand, lead to a more robust medium in order to prevent propagation failure.

From a functional perspective, synchronization of impulses on parallel and adjacent fibers might provide a means to adjust and organize the timing of impulses necessary for coordination and computation of neuronal information. Furthermore, ephaptic interactions may be important in neurological pathophysiology. Indeed, it has been observed that the transmission of impulses occurs from a fiber to an adjacent one when nerves are damaged, as when the nerves end in a neurisma after a nerve crush injury or a nerve compression (Seltzer & Devor, 1979) or when the ionic composition of the extracellular medium is changed (Ramon & Moore, 1978). Demyelination diseases, such as multiple sclerosis, are also a cause of ephaptic connections leading to pathological synchronization (Jefferys, 1995). Finally, ephaptic phenomena have been reported between muscles and motor nerves causing possible cramps and spasms and between cardiac cells, implying a possible involvement of ephaptic coupling in cardiac arrhythmias (Suenson, 1984).

EPIDEMIOLOGY

Throughout human history diseases have played an important role. The black death in Europe in the middle ages is one example, and more recent examples include the flu pandemic of 1918 and 1919 and diseases such as AIDS and various childhood diseases. Additionally, the study of population dynamics in ecology has been greatly advanced by the study of diseases for several reasons. First, the data on the incidence of childhood diseases are both extensive and accurate. Second, the processes involved in the dynamics of childhood diseases (essentially, infection and either recovery or death) are relatively simple and straightforward and well understood.

In particular, many questions of scientific or practical interest can be answered using relatively simple models. A fundamental question is why does a disease die out before everyone has the disease? And, what fraction of the population needs to be vaccinated so a disease can be controlled or eliminated? Answering this question can explain why smallpox was more easily eradicated than other so-called childhood diseases.

Perhaps the simplest epidemic model, which also introduces many of the ideas, is the case of a single epidemic of a disease, first studied in detail by Kermack and McKendrick (1927). We focus here on diseases that are caused by microparasites, so individuals either have the disease or do not, as opposed to diseases caused by macroparasites (such as tapeworms) where the number of infectious agents in individuals needs to be considered explicitly in order to understand the disease dynamics. Different models are needed to understand epidemics and diseases which are endemic (Kermack & McKendrick, 1932).

We assume a constant population size and divide the population into three classes: susceptible, infective, and removed. Since the time scale of an epidemic is much shorter than the time scale of changes in human population sizes, we can simplify the system by ignoring any demographic influences in the simplest model for an epidemic, which corresponds to the assumption of a constant population size. In other words, the population size is assumed constant, and births and deaths are ignored (although there are models that do take this into account) because the time scale of an epidemic is short relative to the time scale of human population dynamics.

We assume that the rate at which susceptibles become infected is simply proportional to the product of the number of susceptible and infective individuals, corresponding to an assumption of random encounters. The rate at which infective individuals recover is assumed to be a constant. Then, with S the number of susceptibles, I the number of infectives, and R the number of removed individuals, the dynamics are given by

$$\frac{dS}{dt} = -\beta SI, \quad (1)$$

$$\frac{dI}{dt} = \beta SI - \gamma I, \quad (2)$$

$$\frac{dR}{dt} = \gamma I. \quad (3)$$

Under the assumption that the total population size N remains constant, we can use the relationship $N = S + I + R$, and reduce the system (1)–(3) to one based on just the first two equations. The phase plane analysis of the resulting system is facilitated by the fact that the formula

$$\frac{dI}{dS} = \frac{\gamma}{\beta S} - 1 \quad (4)$$

is so simple. As first discussed by Kermack and McKendrick (1927), one can solve this system explicitly by integration and using approximations. From this one can see that the solution curves which start with I arbitrarily small return to $I = 0$ before all individuals in the population become infected, or in other words the number of susceptibles at $t = \infty$ is positive.

The qualitative behavior of the system (1)–(3) essentially depends on a single nondimensional parameter, the reproductive number for the disease. The reproductive number is defined as the mean number of infective individuals produced by a single infective individual, which can clearly be calculated by multiplying the rate at which a single infective individual produces new infections by the mean period of infectivity for a single individual. Under our assumptions,

the mean rate of infection is simply βS and the mean infective period is $1/\gamma$. Thus the reproductive number is simply

$$R_0 = \frac{\beta S}{\gamma}. \quad (5)$$

The dynamics are governed by the observation that the number of infectives will increase if $R_0 > 1$ and will decrease if $R_0 < 1$. For the case of a single infective introduced into a population of susceptibles, we can use the total population N instead of S in the formula for R_0 .

The import of the observation about the importance of R_0 (and results from integrating (4)) is typically summarized in the *threshold theorem* which states that there will be an epidemic if the population initially satisfies $R_0 > 1$, which may be a reflection of the population size. From integrating (4) one finds that the total number of individuals who get the disease is dramatically larger if the population is initially above the threshold.

Kermack & McKendrick (1932) further studied the cases of endemic diseases, where it is necessary to take into account the demography of the population, since the time scale is long enough that births and deaths need to be explicitly included. Other more complex systems were also studied (Kermack & McKendrick, 1933).

Modifications of the basic equations have been used to study the dynamics of sexually transmitted diseases, including AIDS. Here, an important modification has been to break up the population into classes based on different encounter rates.

More recent work on disease dynamics has played a central role in population biology, as the data sets for the incidence of childhood diseases in the United Kingdom and many large U.S. cities are among the longest, most accurate, and most detailed records of populations available (Bjornstad & Grenfell, 2001). In particular, the prevaccination dynamics of measles has been carefully analyzed using a variety of approaches, based essentially on extensions of the basic model (Equations (1)–(3)), modified to include a seasonally varying contact rate and, in some cases, stochasticity. Studies of this data has led to important substantial advances in the analysis of the kinds of time series available: relatively short with substantial stochastic influences. Analysis of these time series using nonlinear methods have demonstrated that at least some of the dynamics may be chaotic. Further and more recent efforts have focussed on spatiotemporal dynamics (Rohani et al., 1999) and on applied questions (Keeling et al., 2002) like the recent hoof and mouth epidemic in the UK.

EQUATIONS, NONLINEAR

Nonlinear equations arise in a wide variety of forms in all branches of science, engineering, and technology as well as in other fields such as economics and social dynamics. These include algebraic, differential (ordinary/partial/delay), difference, differential-difference, integro-differential, and integral equations.

Nonlinear algebraic equations such as polynomial (quadratic, cubic, quartic, etc.) and transcendental equations in one or more variables and simultaneous equations have a chequered history. A large number of

root-searching algorithms and methods of solutions are available in the literature.

With the advent of differential calculus in the 17th century, differential equations started to play a pivotal role in scientific investigations. This is particularly so for evolutionary problems, as differential equations are obvious candidates for the dynamical description of natural phenomena. Since most natural processes are nonlinear, it is no wonder that nonlinear differential equations arise frequently in theoretical descriptions (Ablowitz & Clarkson, 1991; Murray, 2002; Lakshmanan & Rajasekar, 2003; Scott, 2003).

Nonlinear ordinary differential equations (ODEs) occur in a wide variety of situations depending upon the nature of the problem. Their solution properties, such as integrability, non-integrability, and chaos, depend upon the order of the highest derivative, number of dependent variables, degree of nonlinearity, whether homogeneous or inhomogeneous, and on the values of the parameters. Some ubiquitous nonlinear ODEs and their significance are indicated in Table 1.

Nonlinear partial differential equations (PDEs) also have a long history dating back to the early days of differential calculus. For example, the basic equations of fluid dynamics, such as the Euler equation and the Navier–Stokes equation, are highly nonlinear. Many of the equations describing nontrivial surfaces in geometry are essentially nonlinear. The properties of solutions of nonlinear PDEs depend heavily on the number of dependent and independent variables, the order, the nature of nonlinearity, and the boundary conditions. However, it is also useful to classify the nonlinear PDEs into nonlinear dispersive and nonlinear diffusive/dissipative types. Further, they can

Name	Equation	Significance
1. Logistic equation	$\dot{x} = ax - bx^2$	Population growth model
2. Bernoulli equation	$\dot{x} + P(t)x = Q(t)x^n$	Linearizable
3. Riccati equation	$\dot{x} + P(t) + Q(t)x + R(t)x^2 = 0$	Admits nonlinear superposition principle
4. Lotka–Volterra equation	$\begin{aligned}\dot{x} &= ax - xy, \\ \dot{y} &= xy - by\end{aligned}$	Population dynamics; exhibits limit cycle
5. Anharmonic oscillator	$\ddot{x} + \omega_0^2 x + \beta x^3 = 0$	Integrable by Jacobian elliptic function(s)
6. Pendulum equation	$\ddot{\theta} + \frac{g}{L} \sin \theta = 0$	Integrable by Jacobian elliptic function(s)
7. Painlevé II equation	$\ddot{x} = 2x^3 + tx + \alpha$	Satisfies Painlevé property
8. Duffing oscillator	$\ddot{x} + p\dot{x} + \omega_0^2 x + \beta x^3 = f \cos \omega t$	Exhibits chaotic dynamics
9. Damped driven pendulum	$\ddot{\theta} + \alpha \dot{\theta} + \omega_0^2 \sin \theta = \gamma \cos \omega t$	Exhibits chaotic dynamics
10. Lorenz equation	$\begin{aligned}\dot{x} &= \sigma(y - x), \\ \dot{y} &= -xz + rx - y, \\ \dot{z} &= xy - bz\end{aligned}$	Prototypical example of chaotic motion
11. Hénon–Heiles system	$\begin{aligned}\ddot{x} + x + 2xy &= 0, \\ \ddot{y} + y + x^2 - y^2 &= 0\end{aligned}$	Hamiltonian chaos
12. Mackey–Glass equation	$\begin{aligned}\dot{x} + \frac{ax_\tau}{(1+x_\tau^{10})} + bx &= 0, \\ x_\tau &= x(t - \tau), \tau : \text{constant}\end{aligned}$	Delay-differential system

Table 1. Some important nonlinear ordinary differential equations ($\dot{} = d/dt$)

Name		Equation	Significance
I	<i>Dispersive Equations</i>		
1.	Korteweg–de Vries equation	$u_t + 6uu_x + u_{xxx} = 0$	Integrable soliton eqn. in (1+1) dimensions
2.	Sine-Gordon equation	$u_{xt} = \sin u$	Integrable soliton eqn. in (1+1) dimensions
3.	Nonlinear Schrödinger equation	$iq_t + q_{xx} + 2 q ^2q = 0$	Integrable soliton eqn. in (1+1) dimensions
4.	Heisenberg ferromagnetic spin equation	$\mathbf{S}_t = \mathbf{S} \times \mathbf{S}_{xx}, \quad \mathbf{S} = (S_1, S_2, S_3)$	Integrable soliton eqn. in (1+1) dimensions
5.	Kadomtsev–Petviashvili equation	$(u_t + 6uu_x + u_{xxx})_x + 3\sigma^2u_{yy} = 0, \quad \sigma^2 = \pm 1$	Integrable soliton eqn. in (2+1) dimensions
6.	Davey–Stewartson equation	$iq_t + \frac{1}{2}(q_{xx} + q_{yy}) + \alpha q ^2q + q\phi = 0, \quad \phi_{xx} - \phi_{yy} + 2\alpha(q ^2)_{xx} = 0, \alpha = \pm 1$	Integrable soliton eqn. in (2+1) dimensions
7.	ϕ^4 equation	$u_{tt} - u_{xx} + u - u^3 = 0$	Nonintegrable equation
II	<i>Diffusive equations</i>		
8.	Burgers equation	$u_t + uu_x - u_{xx} = 0$	Linearizable through Cole–Hopf transformation
9.	FitzHugh–Nagumo equation	$u_t = u_{xx} + u - u^3 - v, \quad v_t = a(u - b)$	Nerve impulse propagation model
10.	Kuramoto–Sivashinsky equation	$u_t = -u - u_{xx} - u_{xxx} - uu_x$	Spatiotemporal patterns and chaos
11.	Ginzburg–Landau equation	$u_t = (a + ib)\nabla^2u + (c + id)(u ^2)u$	Spatiotemporal patterns and chaos

Table 2. Some important nonlinear partial differential equations (suffix denotes partial derivative with respect to that variable)

be classified into integrable and non-integrable PDEs. A select set of such equations along with their significance is given in Table 2.

Another class of interesting nonlinear equations is the so-called difference equations/recurrence equations/iterated maps of the form $\mathbf{x}_{n+1} = \mathbf{F}(\mathbf{x}_n, n)$, where the independent/time variable n takes discrete values $n = 0, 1, 2, \dots$, and $\mathbf{x}_n$ stands for the m dependent variables, while $\mathbf{F}$ is an m -dimensional nonlinear function. These equations often correspond to various finite-difference schemes of nonlinear ODEs/PDEs, such as the explicit Euler or implicit midpoint. For example, the logistic differential equation $dx/dt = ax - bx^2$ can be approximated by Euler’s forward difference scheme as $x_{n+1} - x_n = h(ax_n - bx_n^2)$, where $h > 0$. But nonlinear difference equations can arise as dynamical systems on their own merit as in population dynamics or radioactive decay. The most famous example is the logistic map,

$$x_{n+1} = \lambda x_n(1 - x_n), \quad 0 \leq x \leq 1, \quad 0 \leq \lambda \leq 4,$$

as a prototypical model exhibiting a period-doubling bifurcation route to chaos. A two-dimensional example is the Hénon map, $x_{n+1} = 1 - ax_n^2 + y_n, y_{n+1} = bx_n, a, b > 0$ showing self-similar and fractal nature. Spatiotemporal patterns have been identified in coupled logistic map lattices. There also exist several

integrable families of maps (Kosmann-Schwarzbach et al., 1997): for example, the McMillan map,

$$x_{n+1} + x_{n-1} = \frac{2\mu x_n}{1 - x_n^2}. \tag{1}$$

Other examples include integrable discrete Painlevé equations; Quispel, Robert, and Thompson (QRT) map; and so on. Several integrable nonlinear differential-difference and difference-difference equations also exist (Ablowitz & Clarkson, 1991). The Toda lattice equation

$$\ddot{x}_n = \exp(-(x_n - x_{n-1})) - \exp(-(x_{n+1} - x_n)), \tag{2}$$
$$n = 0, 1, 2, \dots, N$$

is an integrable soliton system. Examples of integrable nonlinear difference-difference equations can be constructed from integrable PDEs.

Nonlinear integro-differential equations arose (Davis, 1962) with the work of Vito Volterra when he introduced a hereditary component composed of the sum of individual factors encountered in the past as a modification to the logistic equation as

$$\frac{dy}{dt} = ay - by^2 + y \int_c^t K(t - s)y(s) \, ds, \tag{3}$$

where a, b, c are parameters and $K(t)$ is a given function. A special case of such an equation is the nonlinear integral equation

$$y(x) = f(x) + \lambda \int_a^b K(x, s, y(s)) ds, \quad (4)$$

where λ is a parameter. Some interesting special cases correspond to $f=0$, $K=\bar{k}(x, t)y^n$ and $f=0$, $K=G(x, t)\exp y$ (Bratu equation), where $\bar{k}$ and G are specified functions. One of the most important nonlinear integro-differential equations in physics is the Boltzmann transport equation for the distribution function $f(\mathbf{r}, \mathbf{v}, t)$ of a dilute gas

$$\left(\frac{\partial}{\partial t} + \mathbf{v}_1 \cdot \nabla_r + \frac{\mathbf{F}}{m} \cdot \nabla_{\mathbf{v}_1}\right) f(\mathbf{r}, \mathbf{v}_1, t) = \int d^3v_2 \int d\Omega \sigma(\Omega) |v_2 - v_1| (f'_1 f'_2 - f_1 f_2), \quad (5)$$

where $f'_i = f(\mathbf{r}, \mathbf{v}'_i, t)$, $f_i = f(\mathbf{r}, \mathbf{v}_i, t)$, $i = 1, 2$. In the integrable soliton case, there exist several interesting integro-differential equations, for example, the Benjamin–Ono equation,

$$u_t + 2uu_x + Hu_{xx} = 0, \quad (6)$$

where Hu is the Hilbert transform.

EQUILIBRIUM

The word *equilibrium* suggests a balance, typically between antagonistic forces, which in turn often implies absence of motion. Consider a rigid rod, which can freely (i.e., with almost no friction) rotate in a vertical plane about a horizontal axis located near one of its

Figure 1. Stable (a) and unstable (b) equilibrium positions of a simple pendulum. (c) The angle θ is measured from the vertical.

ends. Because of gravity, the rod naturally assumes a position where it is suspended from the horizontal axis, and points downward (see Figure 1a). In this situation, the gravity force acting on the rod is balanced by the reaction force at the suspension point, and no motion occurs. The rod is in equilibrium. If displaced a little bit from this position, the rod oscillates about the horizontal axis and, because of friction, eventually returns to its initial position, which is therefore stable. The other equilibrium position of the rod, which is unstable, is that shown in Figure 1b, where the rod points upward. A slight perturbation will take the rod away from this position, toward the stable equilibrium. Consider now a marble rolling on an uneven floor. Typically, it will keep rolling until it stops in a depression of the floor or reaches a wall or a corner of the room. It is clear from this example that depending on the configuration of the floor, there may be more than one stable equilibrium position. As in the case of the rod, there also exist unstable equilibria, which correspond to local maxima of the floor surface. In both of these examples, motion takes place as to decrease the potential energy of the system, which increases with elevation.

From a mathematical point of view, an equilibrium corresponds to a stationary solution of a differential system or a map (see, for instance, Arnol'd, 1992). Quite often, these equations are mathematical models of physical, chemical, or biological systems. Consider the differential equation

$$\frac{d^2\theta}{dt^2} = -\sin(\theta) \quad (1)$$

describing the motion (in dimensionless form) of a simple pendulum, similar to the rigid rod discussed above but without friction. Here, the variable θ measures the angle between the pendulum and the vertical (see Figure 1c). Time-independent solutions of (1) are obtained by setting the right-hand side of this equation to zero. This gives an infinite number of critical points $\theta = 2p\pi$ and $(2p+1)\pi$, where p is an integer. The first family of solutions can be identified with the stable equilibrium of the pendulum discussed above; the second family corresponds to its unstable equilibria.

Nondissipative mechanical systems conserve their total energy. Typically, the latter can be written in dimensionless form as

$$E(u) \equiv \frac{1}{2}(\dot{u})^2 + V(u) = \text{constant}, \quad (2)$$

where u is a time-dependent variable which describes the position of the system and $\dot{u}$ is its derivative. Taking the derivative of (2) with respect to time and dividing by $\dot{u}$ gives

$$\frac{d^2u}{dt^2} = -\frac{dV}{du}. \quad (3)$$

In the case of the pendulum, $u = \theta$ and E is obtained by multiplying (1) by $\dot{\theta} = d\theta/dt$ and integrating over time. It reads

$$E = \frac{1}{2} \left(\frac{d\theta}{dt} \right)^2 - \cos(\theta). \quad (4)$$

The first term on the right-hand side of E corresponds to the (dimensionless) kinetic energy of the pendulum and the second term to its potential energy V . The graph of V as a function of θ is plotted in Figure 2a. We see that solutions $\theta = 2p\pi$ are minima of V , and solutions of the form $\theta = (2p+1)\pi$ are maxima of V . This can be understood in general as follows. Since the right-hand side of (3) vanishes at an equilibrium point, the latter corresponds to an extremum of the potential energy $V(u)$. Because $-dV/du$ can be interpreted as a force, a minimum of V corresponds to a stable equilibrium, for which the force is restoring. Similarly, maxima of V identify unstable equilibria, as illustrated in Figure 2b. In dynamical systems terminology (see, for instance, Guckenheimer & Holmes, 1990), solutions $\theta = 2p\pi$ of (1) are centers and are *neutrally* stable; solutions $\theta = (2p+1)\pi$ are saddles and are unstable. If we now add a friction term to Equation (1), we get

$$\frac{d^2\theta}{dt^2} = -\sin(\theta) - c \frac{d\theta}{dt}. \quad (5)$$

This equation has the same equilibria as (1) but now the total energy E decreases as a function of time, $dE/dt = -c (d\theta/dt)^2$, and as a consequence,

Figure 2. (a) Potential energy $V(\theta) = -\cos(\theta)$ of the simple pendulum. (b) Minima of the potential energy correspond to stable equilibria, whereas maxima describe unstable equilibria. (c) Double-well potential.

the equilibrium corresponding to solutions of the form $\theta = 2p\pi$, where p is an integer, is *globally asymptotically* stable.

In the situation depicted in Figure 2c, V is a double-well potential and the system is *bistable*. Generically, the two minima correspond to different values of the potential energy; the absolute minimum is then the most stable equilibrium of the system; the other minimum corresponds to a metastable equilibrium position.

In the case of maps, equilibria (i.e., stationary solutions) are often called fixed points. For instance, the map

$$u_{n+1} = 2u_n - |u_n|^2 u_n \quad (6)$$

with $u_n \in \mathbb{R}$ has three fixed points, given by $u_n = u_e$ for all values of n , where $u_e = 0$ or $u_e = \pm 1$. They are obtained by substituting the unknown equilibrium value u_e for u_n in Equation (6) and solving for u_e . If we now consider the same map but let u_n be complex, we see that we have, together with the solution $u_e = 0$, a whole family of equilibria, given by $u_e = \exp(i\varphi)$, where φ is an arbitrary real number. This happens because Equation (6) with u_n complex has the following gauge symmetry: if u_n is a sequence of iterates of the map, then so is $u_n \exp(i\varphi)$, but with, of course, a different initial condition, $u_0 \exp(i\varphi)$. More generally, by applying a symmetry of the equation to one of its solutions, one typically obtains another solution. If one starts this iterative process with an equilibrium, a collection of other equilibria is generated. Moreover, if the symmetry is continuous, as it is the case for

the gauge invariance of Equation (6) with u_n complex, a continuous family of relative equilibria is created. Similarly, if the symmetry is discrete, a discrete family of equilibria is obtained. For instance, Equation (6) with u_n real has the symmetry $u_n \rightarrow -u_n$; as a consequence if $u_c = 1$ is an equilibrium, so is $u_c = -1$.

Similar ideas apply to differential equations. Equations (1) and (5) have the discrete symmetry $\theta \rightarrow \theta + 2\pi$. The Landau equation

$$\frac{du}{dr} = u - |u|^2 u, \quad u \in \mathbb{C}, \quad (7)$$

which is the continuous version of Equation (6) with $u_n \in \mathbb{C}$, has the continuous symmetry $u \rightarrow u \exp(i\varphi)$, and its equilibria are given by $u = 0$ and $u = \exp(i\varphi)$, where φ is an arbitrary real number.

EQUIPARTITION OF ENERGY

In 1845, the Scottish scientist John James Waterston submitted a large manuscript outlining a kinetic theory of gases to the Royal Society of London for publication in *Philosophical Transactions*. The central idea of this theory was that heat should be viewed as nothing but the energy associated with the motions of the enormous numbers of molecules, which themselves constitute the gas. Among his results, Waterston noted that "in mixed media the mean square molecular velocity is inversely proportional to the specific weight of the molecules," where the constant of proportionality is to be identified as a measure of thermodynamic temperature. This result is the essence of the Principle of Equipartition of Energy. The manuscript was rejected for publication at the time (as "nonsense, unfit even for reading before the Society") and then published (Waterston, 1893) almost 50 years later when it was (re)discovered by Lord Rayleigh who prefaced the paper with the suggestion that Waterston should be ranked "among the very foremost theorists of all ages."

In the years while Waterston's manuscript lay dormant, the kinetic theory of gases became established, mainly through the collected works of Rudolf Clausius, James Clerk Maxwell, and Ludwig Boltzmann (Brush, 1965, 1966) utilizing statistical methods to describe equilibrium properties. In 1868 Boltzmann obtained one of the most important results of this period, the (Maxwell–Boltzmann) distribution of energy

among the molecules for a gas in thermal equilibrium. Let ε denote the energy of a molecule with r degrees of freedom, and position and momentum coordinates in the range $d\omega = \delta q_1 \dots \delta q_r \delta p_1 \dots \delta p_r$; the number of such molecules is proportional to the product of the extension $d\omega$ and the Boltzmann factor

$$\exp(-\varepsilon/kT).$$

In the Boltzmann factor, $k = 1.38 \times 10^{-16}$ erg/deg is a constant and T is the absolute temperature. The statistical justification for the Maxwell–Boltzmann distribution is that it is the most probable distribution for the distribution of energy among the possible states for a large number of molecules making up a system at constant energy.

Boltzmann derived the Principle of Equipartition of Energy from the Maxwell–Boltzmann distribution in 1871. In Boltzmann's formulation the mean energy associated with each variable that contributes a quadratic term to the total energy of the molecule has the same value $kT/2$. Thus, the mean energy of a molecule in a system is independent of mass—lighter molecules travel faster. From the mean energy per molecule, it is a simple matter to multiply by the total number of molecules to find the total energy and then to differentiate the total energy with respect to the temperature to find the specific heat at constant volume.

For example, for a perfect monatomic gas of N point atoms where $E = \sum_{i=1}^N mv_i^2/2$, there are $3N$ quadratic terms. Thus the internal energy of the gas is $U = 3NkT/2$, and the specific heat at constant volume is $C_V = 3Nk/2$. A simple thermodynamic calculation for the ratio of the specific heat at constant pressure to the specific heat at constant volume yields $\gamma = \frac{5}{3}$ in good agreement with experimental values for the inert gases. In the case of a crystal of N point atoms vibrating about their equilibrium positions according to Hooke's law (harmonic oscillators), there are three quadratic terms for the kinetic energy and three for the potential energy for each particle. Thus, the total internal energy is $U = 3NkT$ and the specific heat is $C_V = 3Nk$, in agreement with the empirical result obtained by Pierre-Louis Dulong and Alexis-Thérèse Petit in 1819.

In 1918 Richard Tolman derived the general Equipartition Principle (Tolman, 1918),

$$\left\langle q_i \frac{\partial \varepsilon}{\partial q_i} \right\rangle = \left\langle p_j \frac{\partial \varepsilon}{\partial p_j} \right\rangle = kT$$

which agrees with Boltzmann's result in the case where ε is a quadratic function of the q_i and p_j but can be applied more generally when ε is not a quadratic function.

Toward the end of the 19th century, some of the predictions from the classical Equipartition Principle were found to be at odds with experimental results.

Examples include the energy distribution from black body radiation, the specific heats of low temperature solids, and the specific heats of diatomic gases. The eventual resolution of these problems played a pivotal role in the upheaval of classical mechanics and the subsequent revolution of quantum mechanics but paradoxically strengthened the atomistic and probabilistic basis on which this principle was founded. The essential new idea of the quantum mechanics is that atoms have sets of discrete energy levels and radiation is absorbed and emitted in discrete quanta. Boltzmann's method of obtaining the Maxwell–Boltzmann distribution as the most probable distribution according to the way that small units of energy could be partitioned was employed by Max Planck in his famous derivation of the radiation law (Planck, 1972) in 1900. The Boltzmann factor is immediately adaptable to the quantum situation. In thermal equilibrium the ratio of the number of particles n_i in one given energy level E_i to the number of particles n_j in another energy level E_j is given by

$$\frac{n_i}{n_j} = \exp\left(-\frac{E_i - E_j}{kT}\right).$$

The word *particle* in this context embraces molecules, electrons, sound waves, light waves, and other dynamical quantities with well-defined energies. As an example, the Boltzmann ratio leads to the average energy of a harmonic oscillator whose quantum energy is an integer multiple of $h\nu$ as

$$\bar{\epsilon} = \frac{1}{2}h\nu + \frac{h\nu}{e^{h\nu/kT} - 1}.$$

In the low-temperature regime this provides reasonable agreement with the experimental result, but it only agrees with the classical Equipartition Principle $\bar{\epsilon} = kT$ at high temperatures, $T \gg h\nu/k$.

The Maxwell–Boltzmann distribution is a stationary or steady-state distribution. It can be derived (Tolman, 1948) from the steady-state micro-canonical ensemble distribution for which the density of ensemble copies in phase space is uniform in a narrow energy range $E, E + \delta E$ but zero elsewhere. The dynamical justification for the Maxwell–Boltzmann distribution then rests upon the (quasi-)ergodic hypothesis that the time spent by the phase space trajectory for the dynamical system in a given region of the energy surface will be proportional to the micro-canonical density of ensemble copies in that region. Thus, from a dynamical perspective, ergodicity is a necessary condition for Equipartition of Energy. It follows that in isolated integrable systems Equipartition of Energy has no dynamical justification.

The Equipartition principle emerged again as a catalyst for change in the mid-20th century when its failure observed in computer experiments (Fermi

et al., 1955) triggered studies into solitons on the one hand and deterministic Hamiltonian chaos on the other (Ford, 1992). The systems investigated by Fermi, Pasta, and Ulam (FPU) could be considered as collections of harmonic oscillators (harmonic modes of vibration) weakly coupled by nonlinear interactions. The expectation of FPU was that energy initially supplied to one of the harmonic oscillators would become uniformly distributed among all harmonic oscillators. Following the FPU experiments, there has been an enormous literature, attempting to recover the equipartition result, particularly for larger nonlinearities and larger numbers of oscillators. Note however that Boltzmann's principle of equipartition of energy predicts uniform energy sharing among the harmonic modes of an isolated linear chain (a result that cannot be justified dynamically), and it does not make predictions for an isolated nonlinear chain. For energy sharing in an isolated nonlinear chain Tolman's general principle of equipartition can be employed, but the result of uniform energy sharing among the harmonic modes should not generally be expected (Henry & Szeredi, 1995). Moreover, nonlinear chains can sustain intrinsic local nonlinear modes that may persist for very long times, and integrable nonlinear chains support nonlinear normal modes that are more fundamental than the harmonic modes.

The principle of equipartition of energy is one of the most fundamental results in the history of the atomistic description of matter. Inconsistencies between this principle and experimental results in different settings have provided a catalyst for some of the most profound theoretical developments in science in the 20th century. A contemporary problem is the failure of the Equipartition Principle in granular materials (Feitosa & Menon, 2002), the resolution of which may play a fundamental role in the development of a comprehensive kinetic theory of granular systems.

ERGODIC THEORY

Ergodic theory is the statistical study of groups of motions of a space, either physical or mathematical, with a measurable structure on it. The origins of ergodic theory can be traced back to the mid-19th century when containers of gas particles were first viewed as sets of randomly moving objects rather than as a collection of individual particles moving under known forces. The word *ergodic* was introduced by Ludwig Boltzmann in the context of the statistical mechanics of gas particles, and it comes from two Greek words *ergon* (work) and *odos* (path).

The mathematical setting in which ergodic theory is studied is as follows. Starting with a space X that represents all possible states of some system which changes over time under known forces, a point $x \in X$ corresponds to one state in the space. The measurable structure consists of a collection of measurable sets $\mathcal{B}$ on X along with a probability measure μ . The measure μ is a function that associates to each set B in $\mathcal{B}$ a number between 0 and 1; this number is the measure of B and we write its measure as $\mu(B)$. A probability measure has the property that $\mu(X) = 1$. Instead of tracking the path of each object in the system, one studies the statistical properties of the motion. The subject evolved from statistical mechanics applied to the study of systems of gas particles moving according to classical laws of physics. In principle, the path of each gas particle can be tracked and its entire history and future can be known; in practice, the complete

determination of the paths of the gas molecules is not feasible.

After t units of time, $F_t(x)$ is the point in X corresponding to where x ends up. If $t \in \mathbb{R}$, then the orbit of x is the set $\{F_t(x) | t \in \mathbb{R}\}$; F_t is called a flow and defines an action of the group $\mathbb{R}$ on X . Frequently, one uses discrete time intervals and writes $T^n(x) \equiv F_n(x)$ for each integer n , so the orbit of x is a discrete set $\{T^n(x) | n \in \mathbb{Z}\}$ and the group acting on X is $\mathbb{Z}$. In the discrete setting the transformation T is the generating map T^1 , and T^n is T composed with itself n times. In classical ergodic theory, the measure μ is preserved under the action; i.e., for any set $A \in \mathcal{B}$, $\mu(A) = \mu(F_t A)$ for all $t \in \mathbb{R}$ or $\mu(A) = \mu(T^n A)$ for all $n \in \mathbb{Z}$. One of the main advantages of the ergodic theoretic point of view is that one can ignore some orbits if they only form a set of measure 0 in the space X ; therefore, one uses the terminology *μ -almost everywhere* (or for μ -a.e. x) to refer to a property that holds on a set of points of measure 1 in X but perhaps fails to hold on some set of measure 0.

Boltzmann's original ergodic hypothesis has come to be known as the statement that *time average equals space average*; he conjectured (in a certain classical setting) that for any integrable function f , for μ -a.e. x ,

$$\lim_{n \rightarrow \infty} \frac{1}{n} \sum_{k=0}^{n-1} f(T^k x) = \int_X f d\mu. \quad (8)$$

In this expression, the time average of f for n time steps along the orbit of x is represented by averaging $f(x)$ with $f(Tx)$, $f(T^2x)$, ..., and $f(T^{n-1}x)$, since each application of T represents the passage of one unit of time (the left-hand side of the expression). The space average of f is obtained by integrating f over the entire space X , giving the right-hand side of the expression. For a flow the ergodic hypothesis is

$$\lim_{t \rightarrow \infty} \frac{1}{t} \int_0^t f(F_s(x)) ds = \int_X f d\mu. \quad (9)$$

The conjecture is false as stated; it only holds when the action is μ -ergodic, and this realization led to the definition of an ergodic action.

The setting of ergodic theory has been greatly enlarged to include the actions of many other groups (Zimmer, 1984). A nonsingular action Φ of a group G on a space $(X, \mathcal{B}, \mu)$ consists of an action of G on X such that the map $\Phi: G \times X \rightarrow X$ is measurable and for each $g \in G$ the map $\phi_g(x) = \Phi(g, x)$ is a nonsingular automorphism of X ; that is, ϕ_g is an invertible measurable transformation and for any $B \in \mathcal{B}$, $\mu(B) = 0$ if and only if $\mu(\phi_g^{-1}B) = \mu(\phi_g B) = 0$. The group operation on G is reflected in the action since $\phi_{g_1 g_2}(x) = \phi_{g_2}(\phi_{g_1}x)$ for all $g_1, g_2 \in G$ and almost every (μ -a.e.) x .

An action is *ergodic* if whenever $\phi_g(A) = A$ for all $g \in G$, then $\mu(A) = 0$ or 1. The study has been extended beyond group actions to the study of ergodic equivalence relations, and the assumption that the measure μ be a probability measure is frequently dropped. One also considers the actions of semigroups when the action being studied is not invertible.

The Birkhoff ergodic theorem for a measure-preserving transformation T states that the limit of the left-hand side in Equation (8) exists for μ -a.e. x , is an integrable function f^* , and $f^*(Tx) = f^*(x)$ for μ -a.e. x . Furthermore, f^* is the constant $\int_X f d\mu$, the space average of f , precisely when the action is ergodic (Birkhoff, 1931). Any point x satisfying the theorem is called a generic point and generates a *typical orbit*. There are many ergodic theorems; perhaps the simplest is the von Neumann ergodic theorem (von Neumann, 1932). By definition, a function $f \in L^2$ if $\int |f|^2 d\mu < \infty$; moreover defining $f \circ T^k(x) = f(T^k x)$, for measure-preserving T , $f \circ T^k \in L^2$ as well. Von Neumann's theorem is also called the Mean or L^2 ergodic theorem because while no individual orbit is tracked (no x appears in the statement), the average difference (L^2 integral) between the time average and the limit function f^* must be small.

Theorem 1. (von Neumann or L^2 Ergodic Theorem) *If T is a measure-preserving transformation and $f \in L^2$, then there is a function $f^* \in L^2$ such that*

$$\int_X \left| \frac{1}{n} \sum_{k=0}^{n-1} f \circ T^k - f^* \right|^2 d\mu \rightarrow 0 \quad \text{as } n \rightarrow \infty.$$

If $(X, \mathcal{B}, \mu)$ is a probability space and the transformation T (or group action) on X is non-ergodic, there is a disintegration or decomposition of μ into measures μ_y , indexed by points y in another probability space Y , with its own measure ρ , such that $\mu(A) = \int_Y \mu_y(A) d\rho$ for every $A \in \mathcal{B}$. Furthermore, the limit function f^* in the ergodic theorems is constant with respect to each measure μ_y ; that is, T is μ_y ergodic for ρ -a.e. y . The decomposition is independent of the function f ; this is referred to as the *ergodic decomposition* of the measure μ with respect to T (Rohlin, 1949). One of the central problems in ergodic theory is to determine when two measure-preserving group actions are conjugate via a measure-preserving isomorphism. To this end, invariants such as entropy and spectral properties have been the subject of much study.

There is a hierarchy of statistical properties associated to ergodic actions, including weak mixing, mixing, K-automorphisms, and Bernoulli automorphisms. As a transformation moves up the hierarchy (in the order listed), the more chaotic the behavior of the system is expected to be.

Applications to Dynamical Systems and Chaos

The simplest example of an ergodic transformation is irrational rotation on the circle with respect to Lebesgue measure. The most random transformation is a Bernoulli shift with an independent identically distributed measure on it; this includes coin tosses.

Overlaps of the topological setting of dynamical systems with ergodic theory exist, and much of ergodic theory highlights the interface between the topological and measurable structure of a group G acting on $(X, \mathcal{B}, \mu)$. In 1935, Hedlund proved the ergodicity of the geodesic flow on the unit tangent bundle of a surface of constant negative curvature; in 1940, Hopf extended the result to establish ergodicity of the geodesic flow on arbitrary manifolds with negative sectional curvature. In this setting the invariant measure is the Liouville measure.

Modern ergodic theory was started by Andrei Kolmogorov with the formal development of Boltzmann's notion of entropy, and developed in the 1960's and 1970's to include many differentiable actions. Applications include fluid dynamics, coding theory, number theory, complex dynamics, and cellular automata.

EULER-LAGRANGE EQUATIONS

In the dynamics of energy conserving systems there are two equivalent formulations: one based on differential equations and the other based on the principle of least action (Goldstein, 1951). At first glance, these two approaches seem to have little in common as one stems from iterating infinitesimal changes along a solution trajectory, whereas the other depends on evaluating all possible paths between two end points and selecting the path with the minimum action.

To see how this goes, consider a simple classical system: the nonrelativistic point particle of unit mass. In three dimensions this particle has three degrees of freedom each labeled by coordinates $q_i(t)$ for $i = 1, 2, 3$. The motion of the particle is determined by a Lagrangian functional $L(q_i, \dot{q}_i)$ which depends on both the position components, $q_i(t)$, and the velocity components, $\dot{q}_i(t)$, of the particle. This functional is

$$L = \sum_i [\dot{q}_i^2/2 - V(q_i)], \quad (1)$$

where $V(q_i)$ is some potential in which the particle moves; thus, the Lagrangian is defined as the difference between the kinetic and the potential energy of the system. The motion of the particle is determined by minimizing the action, which is the time integral of the Lagrangian

$$S = \int_{t_1}^{t_2} L(q_i, \dot{q}_i) dt, \quad (2)$$

and the path taken by the particle is the one for which the action is a minimum. In other words, $\delta S = 0$, where δ implies a differential change in S under a small change in the path.

In calculating the equations of motion, a small variation in the path of the particle $\delta q_i(t)$ is assumed with the endpoints fixed, that is, $\delta q_i(t_1) = \delta q_i(t_2) = 0$. To calculate δS , the Lagrangian is varied with respect to both changes in the position and the velocity

$$\delta S = \int_{t_1}^{t_2} \sum_i \left(\frac{\partial L}{\partial q_i} \delta q_i + \frac{\partial L}{\partial \dot{q}_i} \delta \dot{q}_i \right) dt. \quad (3)$$

Integration by parts of the last term gives

$$\delta S = \int_{t_1}^{t_2} \sum_i \left[\frac{\partial L}{\partial q_i} \delta q_i - \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{q}_i} \right) \delta q_i \right] dt, \quad (4)$$

so the condition $\delta S = 0$ implies that

$$\frac{\partial L}{\partial q_i} - \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{q}_i} \right) = 0 \quad (5)$$

for all i . These are the Euler-Lagrange (EL) equations of motion. For the system of Equation (1), they are $d^2 q_i/dt^2 + \partial V/\partial q_i = 0$, which is Newton's second law.

In some cases the motion is constrained, for example to curves or surfaces. Such a constraint can be expressed as a function $f(q_i) = 0$. Augmenting the Lagrangian to $\tilde{L} = L + \lambda f$ (where λ is called a Lagrange multiplier) and minimizing S with respect to $\tilde{L}$ then yields equations for motion under the constraint (Gelfand & Fomin, 2000). As a simple example, consider the system of Equation (1) with $V = (q_1^2 + q_2^2 + q_3^2)/2$ moving under the constraint $q_1 = q_2$ or $q_1 - q_2 = 0$. Then the EL equations for the augmented Lagrangian $\tilde{L} = L + \lambda(q_1 - q_2)$ are $d^2(q_1 + q_2)/dt^2 + (q_1 + q_2) = 0$ and $d^2 q_3/dt^2 + q_3 = 0$.

An alternative to the Lagrangian formulation (where positions and velocities are the fundamental variables) is the Hamiltonian formulation. Here the positions and momenta (p_i) are independent variables, where

$$p_i \equiv \partial L / \partial \dot{q}_i \quad (6)$$

and a Hamiltonian is defined through the Legendre transformation

$$H(q_i, p_i) \equiv \sum_i p_i \dot{q}_i - L(q_i, \dot{q}_i). \quad (7)$$

Because this Hamiltonian is conserved under the dynamics, it is often interpreted as the energy of a dynamical system. For the example of Equation (1),

$$H = \sum_i [\dot{q}_i^2/2 + V(q_i)], \quad (8)$$

the sum of kinetic and potential energies.

The generalization from a point particle to a three-dimensional field may be viewed as the replacement of $q_i(t)$ by a field amplitude: $\phi(x, y, z, t)$ (Goldstein, 1951). In this case, EL equations can be derived from a variational principle applied to an action integral of the form

$$S = \int \mathcal{L}(\phi, \phi_t, \phi_x, \phi_y, \phi_z) dx dy dz dt, \quad (9)$$

where $\mathcal{L}$ is a Lagrangian density and the subscripts indicate partial derivatives. The condition for minimum

action then gives

$$\frac{\partial \mathcal{L}}{\partial \phi} - \frac{\partial}{\partial t} \frac{\partial \mathcal{L}}{\partial \phi_t} - \frac{\partial}{\partial x} \frac{\partial \mathcal{L}}{\partial \phi_x} - \frac{\partial}{\partial y} \frac{\partial \mathcal{L}}{\partial \phi_y} - \frac{\partial}{\partial z} \frac{\partial \mathcal{L}}{\partial \phi_z} = 0, \quad (10)$$

which is the EL equation in field theory.

A simple example of this field formulation is provided by the sine-Gordon equation in three-dimensional space. The Lagrangian density is given by

$$\mathcal{L} = \frac{1}{2} (\phi_t^2 - \phi_x^2 - \phi_y^2 - \phi_z^2) + (\cos \phi - 1), \quad (11)$$

for which Equation (10) implies

$$\phi_{xx} + \phi_{yy} + \phi_{zz} - \phi_{tt} = \sin \phi. \quad (12)$$

Because not all dynamics conserve energy, the Lagrangian formulation is not applicable to all physically motivated systems. Reaction-diffusion equations, for example, are excluded from this class (Scott, 2003).

EVANS FUNCTION

Traveling waves are one-dimensional patterns that arise in numerous applications, for instance, as defects, flame fronts, nerve impulses, shock waves, and solitons. Typically, traveling waves are only observed in experiments or in numerical simulations if they are stable.

In the early 1970s, Evans developed a number of tools designed to determine the stability of pulses, that is of traveling waves that are localized in space as solutions to a system of partial differential equations (PDEs) (Evans, 1975). The class of PDEs considered by Evans serve as models for the propagation of impulses in nerve axons that include the FitzHugh-Nagumo equation and the Hodgkin-Huxley equations. The strategy to determine the stability of waves consists of two steps: (i) linearize the nonlinear PDE about the wave and calculate the spectrum of the resulting linear operator, and (ii) show that the wave is stable for the nonlinear PDE if the spectrum contains no

unstable elements. This entry focuses on the first step, see Sandstede (2002) for references concerning (ii).

The spectrum of the linearization $\mathcal{L}$ about a pulse or a front is the union of two sets, namely the point spectrum (which consists of all isolated eigenvalues) and the essential spectrum (which is also often referred to as the continuous or radiation spectrum). The essential spectrum can be computed easily as it involves only the homogeneous background states of the pulse or front.

The key problem is therefore to find all isolated eigenvalues in the complement Ω of the essential spectrum in the complex plane. To address this issue for his class of nerve-axon models, Evans constructed an analytic function $D(\lambda)$ (now referred to as the Evans function) that maps the region Ω into the complex plane with the property that $D(\lambda)$ vanishes precisely at isolated eigenvalues of the linear operator $\mathcal{L}$. In fact, the order of a root λ_* of the Evans function $D(\lambda)$ coincides with the algebraic multiplicity of λ_* as an eigenvalue of $\mathcal{L}$. Here, ℓ is the order of a root λ_* of $D(\lambda)$ if the first $\ell - 1$ derivatives of $D(\lambda)$ vanish at λ_* but the ℓ th derivative does not.

Note that, if the underlying PDE is invariant under space translations, then $\lambda = 0$ is an eigenvalue. The corresponding eigenfunction is given by the spatial derivative of the wave. Hence, if $\lambda = 0$ is not in the essential spectrum, the Evans function $D(\lambda)$ vanishes at $\lambda = 0$. Proving linear stability of a pulse, therefore, amounts to calculating the Evans function $D(\lambda)$ and showing that it does not have any zero in the closed right half-plane except possibly a simple zero at $\lambda = 0$.

The derivative $D'(0)$ is actually given by the Mel'nikov integral, computed with respect to the wave speed, c , of the pulse. This integral measures how the stable and unstable manifolds of the background state intersect as the wave speed c of the pulse is varied. In other words, if the existence problem of the wave is understood well enough, then $D'(0)$ is computable.

This can be exploited as follows. The Evans function $D(\lambda)$ is, in fact, real whenever λ is real, and $D(\lambda)$ can be normalized so that $D(\lambda) > 0$ for all sufficiently large $\lambda \gg 1$. Here, λ is the temporal growth rate so that unstable eigenvalues have positive real part. Thus, if $D'(0) < 0$, then the pulse is necessarily unstable with an odd (and therefore nonzero) number of unstable real eigenvalues. Consequently, the derivative $D'(0)$ of the Evans function provides a parity instability index.

The function $D(\lambda)$ introduced by Evans was then later used by Jones and by Yanagida to prove that the fast pulse arising in the FitzHugh-Nagumo equation is stable. Both proofs used the parity index introduced above: after establishing that there is precisely one eigenvalue besides $\lambda = 0$ that lies close to the imaginary axis or in the right half-plane, a computation of the parity index at $\lambda = 0$ showed that it is positive, so that the other eigenvalue must lie in the left half-plane.

Figure 1. The three illustrations show typical spectra of the linearization about (a) a stable pulse in a dissipative PDE, (b) a soliton in an integrable system, and (c) a viscous shock wave. The horizontal and vertical axes are $(\text{Re } \lambda, \text{Im } \lambda)$. The point and essential spectrum are shown as discs and lines, respectively.

Alexander et al. (1990) developed the Evans function further and also related it to certain topological invariants. Since then, Evans-function calculations have been utilized in various applications, for instance, in nonlinear optics, plasma physics, and thin films (Sandstede, 2002; Zumbrun, 2001).

An important class of PDEs to which the Evans function has been applied is singularly perturbed equations that exhibit two different spatial scales. In this situation, the Evans function can often be calculated from the Evans functions for the slow and the fast subsystem (Doelman et al., 2002).

The Evans function is also a useful tool for investigating the stability of multi-hump pulses, or n -pulses, which are composed of n widely separated copies of a primary pulse. If the primary pulse is stable, so that $\lambda = 0$ is a simple eigenvalue, then such an n -pulse has exactly n critical eigenvalues near the origin which encode the interaction properties of the n individual pulses. These eigenvalues can be calculated using the Evans function (Sandstede, 2002).

The original construction of the Evans function works only outside of the essential spectrum. For Hamiltonian PDEs, the essential spectrum of stable pulses lies on the imaginary axis, see Figure 1(b). Thus, it is possible that eigenvalues move out of the essential spectrum and into the right half-plane once a small perturbation is added to the underlying PDE. The points in the essential spectrum from which such eigenvalues can potentially emerge and the exact location of the bifurcating eigenvalues for concrete perturbations can be found by extending the Evans function across the essential spectrum. For integrable PDEs such as the Korteweg–de Vries or the nonlinear Schrödinger equation, it is possible to compute the extended Evans function explicitly using inverse scattering theory (see Kapitula & Sandstede (2002) for references).

Similar issues occur for the linearization about viscous shock waves where the essential spectrum always touches the origin, see Figure 1(c). An extension of the Evans function across the essential spectrum to a full neighborhood of $\lambda = 0$ allows one to generalize the parity instability index, given by an appropriate sign con-

dition on the derivative $D'(0)$, to viscous shocks. In addition, the extended Evans function plays an important role in the nonlinear stability analysis of viscous shocks (Zumbrun, 2001).

EVAPORATION WAVE

Under special conditions a liquid can be superheated to a few hundred degrees Celsius above its nominal boiling point. The thermal energy associated with this excess temperature can be released by rapid evaporation, also called a *vapor explosion*. The largest explosions on Earth are vapor explosions in the form of volcanic eruptions. For example, the Mount St. Helens blast was estimated at 400 Mtons TNT equivalent (Decker & Decker, 1981), which is nearly the sum of all worldwide nuclear explosions to date (about 500 Mtons).

Vapor explosions also pose a hazard in industry. In one incident, 100 lb of molten steel fell into an open trough containing 78 gallons of water. The resulting explosion killed one person and injured many, cracked the 20-in. thick concrete floor, and shattered 6000 panes of glass (Reid, 1976). If a vapor explosion involves a flammable liquid, then the physical explosion can transition to a more powerful chemical explosion.

An *evaporation wave* is a vapor explosion that proceeds across the system with an identifiable propagation velocity. Evaporation waves are an interesting example of self-organized dynamical complexity and comprise a controlled form of vapor explosion that facilitates the detailed study of liquid fragmentation and dispersal mechanisms.

Liquid superheating is caused by cohesion between molecules. Hence, bubbles—even very small

Figure 1. Existence region for superheated liquid from the Redlich–Kwong (R–K) equation of state. R–K predicts universal behavior in a reduced coordinate system.

ones that reside in most liquids under normal conditions—comprise weak spots that inhibit superheating. Even a completely pure liquid can only be superheated to a point, called the superheat limit, where it becomes mechanically unstable. The theoretical superheat limit occurs at a locus of states called the *spinodal curve* (Debenedetti, 1996). Superheated liquid can exist between the saturation and spinodal curves as shown in Figure 1. The amount of superheat is quantified by the excursion of the liquid state from the saturation curve, for example, the degree ΔT by which the liquid temperature exceeds the equilibrium temperature at its pressure.

The specific enthalpy required to evaporate a liquid is the latent heat of evaporation L . A superheated liquid stores an excess specific enthalpy $C_p \Delta T$, where C_p is the liquid specific heat at constant pressure. The Jakob number, $Ja \equiv (C_p \Delta T)/L$, is equal to the liquid mass fraction χ that can evaporate adiabatically at constant pressure. If $Ja > 1$ then complete evaporation can occur. This condition is possible in *retrograde* liquids, which are those possessing a sufficiently large specific heat (Thompson et al., 1986). Nowhere near complete evaporation is required to produce quasisteady evaporation waves. However, sufficient evaporation must occur so that the liquid phase is swept along by the vapor; otherwise, the upstream liquid will cool and the process will quench.

The first mention of an evaporation wave appears to have been by Terner (1962), who performed vertical shock tube experiments on heated water. Terner believed that an evaporation wave followed depressurization, though he did not definitively show it.

The first direct observation appears to have been by Friz (1965), who studied the expulsion of superheated water from a vertical glass tube into the atmosphere. The tube was sealed on top by a diaphragm, and the water was heated to temperatures from 105°C to 125°C. The gas space above the water was pressurized to 3.5 bar, whereupon a cutter was activated to puncture the seal. Friz describes that upon depressurization “a

Figure 2. Schematic diagram of an evaporation wave (a), and a photograph of an evaporation wave in freon-12 at 20°C (b). The front is moving down at 0.6 m s^{-1} .

great number of bubbles” formed throughout the water column. An “acceleration front” several centimeters thick then propagated into the bubbly mixture at $1\text{--}2 \text{ m s}^{-1}$, transforming it into a spray that was ejected upward. The many bubbles were probably caused by pre-pressurization, which increased the amplitude of the initial expansion wave so that it reflected from the test cell base in tension, causing cavitation.

Grolmes and Fauske (1970) performed similar experiments in heated water, freon-11, and methanol. Their configuration was like Friz’s, except that (i) the initial pressure was the vapor pressure, and (ii) the fluid was expelled into a nearly evacuated reservoir. By paying careful attention to the liquid purity and test cell cleanliness, they were able to suppress *all* nucleation within the liquid column. Upon depressurization boiling erupted on the liquid surface and proceeded with sufficient vigor to expel the generated spray from the container as depicted in Figure 2a. The boiling surface receded at a constant average rate of $0.3\text{--}0.5 \text{ m s}^{-1}$, depending on the liquid and conditions.

Thompson et al. (1987) performed similar experiments on the retrograde fluorocarbon perfluoro-*n*-hexane (C_6F_{14}). At the highest (nearly critical) temperatures, the lead expansion wave attempted to lower the pressure past the superheat limit, whereupon homogeneous nucleation erupted and blocked the drop. An approximate plateau was maintained near the spinodal, into which a slower evaporation wave propagated in a manner similar to Friz’s. Such *wave splitting* occurs when material properties abruptly change within the wave, in a way that lowers the sound speed. At lower temperatures, homogeneous nucleation likely erupted upon reflection of the initial expansion wave from the test cell base, and an evaporation wave initiated after the reflected wave reached the free surface. The waves became progressively less distinct as the initial temperature was lowered, presumably because heterogeneous nucleation from the metal side-walls and the transducer ports became increasingly important.

Shepherd and Sturtevant (1982) performed experiments on butane drops that were heated slowly in an ethylene glycol host fluid to the superheat limit

($\Delta T = 105^\circ\text{C}$), whereupon they exploded with a sharp “crack.” High-speed photographs showed that evaporation initiated at a single nucleation site at or near the drop surface and spread into pure liquid as a miniature evaporation wave resembling Grolmes and Fauske’s. Thus, heating to the superheat limit has produced waves in pure liquid, whereas depressurizing to the superheat limit has produced waves in bubbly liquid.

Shepherd and Sturtevant suggested that the *Landau instability* of premixed flames was the essential fragmentation mechanism. Frost and Sturtevant (Frost, 1988) repeated the exploding droplet experiments in pentane, iso-pentane, and ethyl ether. They obtained several photographs in which the evaporating interface had a mottled texture resembling an orange peel. This suggested that they had caught the interface at the early stages of instability, which they believed grew to the point of pinching off droplets to produce the observed rough-looking interfaces and spray flow. About the same time Mesler (1988) proposed that the *secondary nucleation* mechanism of surface boiling—whereby receding film-caps from ruptured bubbles strike the liquid surface and entrain vapor to create new nucleation sites—was responsible.

Hill and Sturtevant (Hill, 1991) performed Grolmes and Fauske-type experiments in freons 12 and 114, with the goal of observing detailed propagation mechanisms. Figure 2b is a photograph from that study. Several observations suggested that a three-step cycle occurs: (i) bubbles grow at the leading edge in accordance with classical theory; (ii) these are consumed en masse by fragmentation waves that sweep around the bubbly layer transversely to the main propagation at speeds of order the axial flow, and which shatter the superheated interstitial liquid into droplets; (iii) a small fraction of the droplets are propelled forward to strike the leading edge and nucleate new bubbles à la Mesler. Whether such behavior extends toward the superheat limit, or whether a nucleation-free evaporative instability dominates at some point, is unknown.

Simões-Moreira and Shepherd (1999) performed similar experiments in heated dodecane ($\text{C}_{12}\text{H}_{26}$)—a highly retrograde liquid—with the intention of observing complete evaporation waves. For $\text{Ja} > 1$ a simple plane evaporation wave, or a convoluted but simply connected surface like Frost’s “orange peel,” would be energetically admissible. Instead they observed a scenario qualitatively like previous experiments, except that the droplets evaporated in the downstream flow.

From a gas-dynamic viewpoint an evaporation wave is analogous to a flame in a combustible mixture. Both are classified as *deflagrations*, or *exothermic discontinuities*. The ideal theory (e.g., Hayes, 1958) considers a plane, steady wave. The conservation equations for mass, momentum, and energy are applied

between the upstream state **1**, and an arbitrary state in the reaction or evaporation zone. The flow is assumed to be one-dimensional (no turbulence), and viscosity and heat conduction are neglected. Eliminating the fluid velocities between the three conditions yields the Hugoniot curve $\mathcal{H}$, which specifies the locus of possible downstream states given **1**:

$$h_1 - h(v, P) = \frac{1}{2}(P_1 - P)(v_1 + v), \quad (1)$$

where h is the specific enthalpy, P is the pressure, and v is the specific volume. Combining the mass and momentum equations gives the Rayleigh line $\mathcal{R}$:

$$\frac{P - P_1}{v - v_1} = -(\rho_1 V_w)^2 = -\dot{m}^2, \quad (2)$$

a line in P - v space with negative slope equal to the square of the mass flux $\dot{m}$. Since the same value of $\dot{m}$ applies throughout the structure of the steady wave, $\mathcal{R}$ traces the locus of states in the reaction or evaporation zone. Steady wave solutions are given by the intersection of $\mathcal{R}$, with $\mathcal{H}$ evaluated at the end state **2**.

We now specialize the analysis to an evaporation wave with pure (or nearly pure) upstream liquid, with a two-phase downstream mixture described by

$$h = h_l(1 - \chi) + h_v\chi \quad \text{and} \quad v = v_l(1 - \chi) + v_v\chi, \quad (3)$$

where χ is the mass fraction of vapor, and l and v denote the liquid and vapor phases. We neglect slip between the two phases keep to and invoke four additional assumptions that are each usually accurate to a percent or better: (i) the liquid enthalpy is conserved upon depressurization from the initial state **0** to the established upstream state **1** ($h_0 = h_1$); (ii) the liquid density is constant throughout ($\rho_0 = \rho_1 = \rho_l = \rho_{l2}$); (iii) the vapor density is small compared with the liquid density ($\rho_v \ll \rho_l$)—true except near the critical point; (iv) the kinetic energies are small compared with the thermal energy ($\chi_2 = \text{Ja}_2$).

In the evaporation zone the liquid droplets are still somewhat superheated, with bulk enthalpy (averaged over a cross-section) h_l . Motivated by the reaction progress variable used in combustion, we define an *evaporation progress variable*, $0 \leq \lambda \leq 1$:

$$\lambda \equiv \frac{h_0 - h_l}{h_0 - h_{l\phi}(P)}, \quad (4)$$

where $h_{l\phi}(P)$ is the equilibrium liquid enthalpy. The Jakob number is then written as

$$\text{Ja}(P) \equiv \frac{h_0 - h_{l\phi}(P)}{h_v(P) - h_{l\phi}(P)}. \quad (5)$$

Figure 3. Thermodynamic construction for an evaporation wave—the liquid expansion isentrope, Hugoniot curve, Rayleigh line, and Chapman-Jouguet point.

Combining Equations (3b)–(5) with the energy equation gives an implicit formula for $\mathcal{H}$:

$$v = v_0 + \frac{v_v(P) \lambda \text{Ja}(P)}{1 - \text{Ja}(P)(1 - \lambda)}. \quad (6)$$

Equation (6) is plotted in Figure 3 for several values of λ . A particular $\mathcal{R}$ is overlaid, which intersects $\mathcal{H}$ in two places. The high-pressure intersection at **2w** is the *weak solution*; the low-pressure intersection at **2s** is the *strong solution*. One can show that the end state **2** is subsonic for the weak branch and supersonic for the strong branch. In progressing along $\mathcal{R}$ from **1** to **2w**, the local state crosses increasing values of λ . This is a physically realizable process. But there is no physical way for evaporation to proceed beyond **2w** to **2s**—which is why strong deflagrations are not observed.

In the special case where $\mathcal{R}$ intersects $\mathcal{H}$ at the tangency point the emerging flow is exactly sonic; this is the Chapman-Jouguet (**cj**) point. It is clear from Equation (2) and Figure 3 that for a given **1**, **2cj** defines the maximum allowable wave speed. In some experiments, the test cell is *choked*, which corresponds to sonic outflow in the laboratory frame. In an evaporation wave, the two-phase flow speed is much faster than the wave speed, such that the difference between the laboratory and wave frames is negligible. Therefore, if an unobstructed test cell of constant cross-sectional area is choked, the wave can be considered **cj**.

Combining $\mathcal{R}$ with $\mathcal{H}$ evaluated at **2** gives an explicit equation for the wave speed:

$$V_w = \sqrt{\frac{v_0 \delta P_2}{\text{Jk}(P_2)}}, \quad \text{where } \text{Jk}(P) \equiv \text{Ja}(P) \left(\frac{v_v(P)}{v_0} \right)$$

and

$$\delta P \equiv P_1 - P. \quad (7)$$

Figure 4. Plot of the evaporation wave speed relation, Equation (7), for freon-12.

δP_2 is the overall wave pressure-amplitude, one measure of its strength. Jk is a useful alternative definition of the Jakob number that arises about as frequently as Ja , and which unfortunately goes by the same name (and usually the same symbol).

The liquid initial conditions v_0 and h_0 , and the external reservoir pressure P_r , are set a priori and remain essentially unchanged after depressurization. Assuming that the test cell is long enough for equilibrium to be achieved at or before the exit: if the flow is unchoked (weak solution), then $P_2 = P_r$; if the flow is choked (**cj** solution), then $P_2 > P_r$ and a sonic condition applies that specifies P_2 . But P_1 , and therefore δP_2 , is unknown.

Figure 4 plots Equation (7) for various values of P_1 . Each curve has a velocity maximum, representing its own **cj** solution, the locus of which is given by

$$V_{w\text{cj}}(P_2) = \sqrt{\frac{v_0}{-d\text{Jk}/dP_2}}. \quad (8)$$

Predicted and measured wave speeds can deviate by up to 50%. Two issues likely dominate. First, the theory assumes the flow to be strictly one dimensional, but Hill's experiments show that the transient lateral flow velocity in the evaporation zone is of order the mean axial velocity. This results in a higher-than-calculated pressure drop. Second, evaporation is very rapid where fragmentation occurs, but slows downstream where droplets are convecting. Thus, the end state **2** may not exist within the tube.

To close the theory—to calculate the wave speed without measuring P_1 —we must add a statement about the physical mechanisms peculiar to evaporation waves. This task is actually simpler for waves in bubbly liquids than for waves in pure ones. For Thompson et al.'s highest-temperature experiments, the upstream state was essentially at the superheat limit, which can be computed from initial conditions. In Friz's experiments, there was time for multiple acoustic reflections in the upstream liquid. He assumed P_1 to be the equilibrium value at the initial temperature, which gave reasonable results.

For waves in pure liquids there is no upstream nucleation to modulate the pressure, and one must address the boiling dynamics in the evaporation zone. The problem is analogous to the calculation of flame speed, which is controlled by the rate of heat conduction (and often convection) from the reaction zone to the reactants. This is where transport properties such as thermal and mass diffusivity enter. No such physically based model exists for evaporation waves, although Reinke and Yadigaroglu (2001) have proposed an empirical correlation based on existing data.

EXCITABILITY

Nineteen century natural history identified irritability—the active response to stimulation—as a characteristic

of living systems; this vague concept has developed into excitability, a characteristic of some nonlinear systems.

An excitable system has a stable resting state, and the response to a small brief perturbation is small, with an amplitude that varies smoothly with the perturbation amplitude. The response to a sufficiently large perturbation, above a threshold, is qualitatively different, undergoing a stereotyped, large amplitude excursion in at least one of the state variables before return to the resting state. For a spatially extended excitable system, the subthreshold response is localized while the suprathreshold response is a traveling wave, or traveling wave train. This dynamics—a stable steady state (a mathematical, but not thermodynamic equilibrium), a threshold, and a return to the steady state—requires at least two processes, a fast nonlinear excitation and a slower recovery process.

The excitation process can be exemplified by the bistability of a candle. The unlit candle is stable, and the threshold for igniting the candle arises from a positive feedback, with heat melting and vaporizing the wax, and the vapor providing the fuel sustaining the flame. This positive feedback loop gives the all-or-none nature of the flame—either it is self-sustaining or not, and the threshold separates these two states. The burnt candle is stable; there is no recovery process.

An example of excitation and recovery is provided by the nerve impulse, where the resting state potential is stable and the energy required for the action potential is obtained from the electrochemical gradients across the membrane. The voltage dependence of the Na^+ conductance provides the positive feedback. Recovery is by the slower, voltage-dependent K^+ conductance, and propagation by spread of depolarization along the fiber (Cole, 1968; Aidley, 1998). In both these examples, the spatial spread of activity can be considered as traveling-wave solution of a reaction-diffusion equation in which there is a balance between the active nonlinear term and the diffusive term. In typical chemical excitable systems, all the variables diffuse, with similar diffusion coefficients; in nerve and muscle excitation only the fast excitation variable (transmembrane voltage) spreads and there is only one nonzero diffusion coefficient. The velocity of the traveling-wave solution varies as the root of the diffusion coefficient.

The simplest excitable dynamical system has two kinetic variables, a fast excitation u and a slower recovery v

$$\varepsilon \, du/dt = f(v, u), \quad dv/dt = g(v, u), \quad (1)$$

and the nullcline for the fast excitation system has the characteristics of a cubic that is, for a range of u values the solution of $f(v, u) = 0$ has three branches. If, as in Figure 1, the nullclines have a single intersection

Figure 1. State space of two-variable excitable system, with u the fast excitation variable and v the slower recovery variable. There is a stable equilibrium and a single suprathreshold response.

on the left branch, there is a single globally stable, but excitable, steady state. A large enough perturbation gives a trajectory that jumps to the right branch, moves slowly close to the right branch, and then jumps back to the left branch, returning slowly to rest. If the nullclines intersect on the central branch the resultant equilibrium can be unstable, and the system is no longer excitable but oscillatory.

The key concepts of excitability—threshold and all-or-none response—came from the physiology of nerve and muscle tissue. Nerve and muscle are electrically excitable tissues; their excitability is electrochemical, due to nonlinear membrane current-voltage relations produced by voltage-dependent conductances. The suprathreshold response is the action potential that acts as a trigger, where the intensity of the response is determined by the rate of action potentials. Repetitive activity—that can be idealized as a periodic response—is a biologically significant behavior and may be forced, by inputs to an excitable system, or endogenous, as in a pacemaking system, due to stable limit cycle surrounding an unstable equilibrium when the equilibrium state loses its stability at a Hopf bifurcation as a parameter (say, an applied current or maximal membrane conductance) is changed. Also rate coding phase synchronization effects can be significant—synchronization of bursting discharges in the mammalian central nervous systems provides a candidate mechanism for cognitive effects (Eckhorn, 1999). In spatially extended cells, there can be repetitive traveling-wave trains—effectively one-dimensional in a nerve fiber, and three-dimensional in heart muscle. In the heart three-dimensional scroll waves provide the mechanism for re-entrant arrhythmias that can lead to sudden cardiac death. Some intracellular systems show chemical excitability: a localized increase in intracellular $[Ca^{2+}]$ can trigger calcium-induced calcium release from intracellular organelles, producing intracellular calcium oscillations, or traveling waves. An example is a $[Ca^{2+}]$ wave triggered by fertilization of

an oocyte (Dupont & Goldbeter, 1997). Chemical excitability, via cyclic AMP triggering cellular release of cyclic AMP, underlies the wave phenomena seen in the aggregation of the slime mold *Dictyostelium*, a simple example of morphogenesis (Tyson & Murray, 1989). In all these biological examples, high-order, mechanistically detailed stiff systems of equations have been developed, validated, and investigated numerically, but much of the essential phenomenology can be captured by low-order caricatures. Simple models of biological populations can also show excitable behavior, for example, the initiation of an epidemic.

The Belousov–Zhabotinsky reaction, initially developed as an oscillatory organic reaction as an analogue of biochemical oscillations, was the first of several autocatalytic chemical reactions that, in a flow reactor with concentrations that allow bistability, addition of a feedback species can lead to oscillations (Sagues & Epstein, 2003). These chemical oscillatory systems, in thin films and bulk media, also show traveling waves—target patterns, spirals, and scrolls—and with some parameter values are excitable. Models of autocatalytic processes with cubic excitable kinetics are widely used to represent oscillatory and wave phenomena in chemistry, especially combustion problems (Gray & Scott, 1990).

EXCITONS

Traditionally, an exciton is defined as a quantum of electronic excitation energy traveling in a periodic structure, whose motion is characterized by a wave vector. It is generated when an electron from a filled electronic orbital of a molecule is transferred through an optical or electrical excitation to a high-energy unoccupied electronic orbital, leaving behind it a hole. Coulomb interaction binds the excited negative electron and the positively charged hole producing an electrically neutral bound state, and this bound electron-hole pair is the exciton. Once created the exciton can be destroyed through emission of light (radiative recombination) or heat (nonradiative recombination), electron-hole separation (exciton dissociation), and subsequent absorption of the electron by an acceptor site (electron transfer). It can change its spin state through intersystem crossing, while at high excitation densities, excitons can mutually collide and dissociate (exciton-exciton annihilation). Furthermore, the whole excitation can move to other sites leading to energy transfer, one of its most important properties.

Excitons occur in molecular crystals, inorganic semiconductors, and conjugated polymers. Three different types of excitons are known. The Frenkel exciton is an electronic excitation of a single molecular unit with both electron and hole located on the same molecule. As any molecule is equally likely to be excited and if there is nonzero coupling between adjacent molecules, this exciton is transferred from one molecular unit to another. Frenkel excitons appear in ionic, molecular, and noble gas crystals having a typical binding energy of 1 eV. In the Wannier exciton the electron-hole distance is much larger than the lattice spacing, and the Coulomb interaction gets screened by the crystal dielectric constant forming a hydrogen-like bound system. They appear mostly in inorganic semiconductors and have a small binding energy of about 0.1 eV and a large radius of typically 50 Å. Finally, the charge-transfer exciton is intermediate between Frenkel and Wannier excitons with an electron-hole distance of a few lattice spacings.

Although excitons are neutral they can be found in definite spin states depending on the relative orientation of electron and hole spins. For antiparallel electron-hole spins a singlet exciton with total spin zero is formed with short lifetime of the order of picoseconds due to fast decay through an optically allowed transition leading to fluorescent emission from this state. There are also three degenerate spin one states leading to a triplet exciton that produces emission termed "phosphorescence." Optical transitions between triplet excited and single ground state are not allowed due to the forbidden spin flip, resulting in conjugated polymers in triplet

exciton lifetime of the order of milliseconds at low temperatures. Thermal energy assists triplet motion and at higher temperatures exciton motion process in an incoherent diffusive mode, although some quantum mechanical coherence may be retained. Coherent exciton dynamics at finite temperatures is investigated theoretically through generalized Langevin equations.

Self-trapped excitons (STEs) form a special class of excitations that involve excitons coupled strongly to vibrational degrees of freedom of molecules. Low-dimensional and, in particular, quasi-one-dimensional materials are ideal systems for studying STEs because reduced dimensionality results in strong electron-phonon interaction. Systems under experimental study include halogen-bridged MX materials, where X is a halogen (chlorine, bromine, etc.) and the metal is, for instance, platinum or crystalline hydrogen-bonded acetanilide (ACN).

The STE can be of electronic or vibrational nature if, in the latter case, specific vibrational modes couple strongly to other phonon system modes leading to vibron excitons. In ACN, C=O as well as NH stretching modes have been linked with STEs through the temperature dependence of specific peaks in their absorption spectra, while in the metal-halogen material PtCl, resonant Raman spectroscopy experiments have indicated the existence of self-localized modes.

From a more formal point of view, STEs can be classified as polarons, solitons, or (discrete) breathers, and depending on their specific nature, they may have some differences in their precise physical properties. A generic mathematical model for exciton self-trapping is provided by the discrete nonlinear Schrödinger equation (DNLS) or discrete self-trapping equation

$$i \frac{d\psi_n}{dt} = \varepsilon_n \psi_n + V(\psi_{n+1} + \psi_{n-1}) - \gamma |\psi_n|^2 \psi_n, \quad (1)$$

where ψ_n is the probability amplitude for an exciton to be located in a molecular unit at a crystal site n with local energy ε_n , V is the nearest neighbor overlap, and γ is proportional to exciton-phonon coupling. In this approximate, semiclassical description, the nonlinear term in the equation arises from strong electron-phonon coupling in the original exact problem that can be introduced, for instance, by a model such as the Holstein model for molecular crystals. The conserved number $\sum_n |\psi_n|^2 = N$ of the DNLS equation corresponds to the number of excitation quanta present in the system. In the weak coupling limit where $V \rightarrow 0$, the STEs of DNLS are completely localized in a given site with energy equal to

$$E_N = N\varepsilon - \frac{\gamma}{2} N^2, \quad (2)$$

where all local site energies are taken to be identical, that is, $\varepsilon_n = \varepsilon$ for all n . The energy of the STE is thus lower than $N\varepsilon$, the energy of the delocalized exciton and also red-shifted by an amount that grows quadratically in the number of quanta N . These spectral features have been observed experimentally in spectra of both PtCl and ACN as well as in other systems. Precise theoretical analysis of resonant Raman spectra of PtCl as well as femtosecond infrared pump-probe spectroscopy experiments in ACN that go beyond the weak coupling DNLS energy in Equation (2) have demonstrated the existence of STEs in these systems. In the case of ACN, an amide-I exciton lifetime of the order of 2 ps was found. If, as originally conjectured by Davydov, similar modes with larger lifetimes exist in biological macromolecules such as proteins, STEs may participate in energy transfer processes of biological significance.

EXPLOSIONS

The English word *explode* comes from the Latin word *explodere*, which means to drive an actor from the stage by rhythmic clapping. In applied science, a sudden deposition of energy leads to an explosion. Since on a streamline of a flow we have $dE/dt = -p dv/dt$ (where E is internal energy, t is time, p is pressure, and v is volume), rapid deposition of energy will give high pressure, or rapid motion as volume expands, or both. How large and how rapid the energy deposition must be to have an explosion depends on external circumstances, so the concept of explosion is investigated here by looking at some examples.

Low Explosives and Propellants

The words *energetic materials* are used to describe substances that have fuel and oxidizer in the same molecule or in separate molecules intimately mixed. Production and purification of potassium nitrate (KNO_3) were the keys to making materials that burned rapidly and could be used for fireworks, frightening enemies, setting enemy ships on fire, and entertainment at fairs. After 1300 AD, these materials were used in guns, and the mixtures were improved for better performance. High-strength black powder is about six parts of potassium nitrate and one part each of charcoal and sulfur. Black powder has been replaced by smokeless powders made from nitrocellulose or nitrocellulose with nitroglycerin, with various additives. Modern rocket motors usually use a coarse mixture of ammonium perchlorate (NH_4ClO_4) as oxidizer, and rubber, aluminum powder, and high explosive molecules as fuels. Black powder was used in mining from 1650 to 1900; it has since been replaced by high explosives.

All of these materials deliver their energy by burning, which is also called deflagration. That is, energy is transferred from the reacting region forward to ignite the unreacted material mainly by heat conduction. The wave speed of the flame is slow compared with the speed of sound, so that the pressure is nearly constant in the flame. The distance from the reacting region to the wave front varies with the pressure, so the speed of the flame and its rate of release of energy depend on the external confinement. In a mine, the apparent power of black powder varies with the strength of the rock and the existing cracks in the rock. The powder in a gun is usually in the form of separate pellets or grains, and the rate of burning depends on the exposed surface area that supports the flame. As the projectile moves along the barrel, the volume to be occupied by the gases increases at an accelerating rate. It is advantageous to have the rate of burning also accelerate, and this is accomplished by shaping the grains. For example, the grains may be in the form of cylindrical pellets with a number of holes parallel to the axis. As the pellet burns, the holes are enlarged, exposing more area and accelerating the rate of gas production.

High Explosives

High explosives are also energetic materials with the fuel and oxidizer in intimate mixture or in the same molecule. They explode by a process called detonation, and the speed of the reaction is 100,000–10,000,000 times faster than burning in the same material. The rapid reaction produces extremely high pressures and speeds. It also makes the detonation process almost independent of confinement or boundary effects. High explosives detonate the same way every time, without being influenced by exterior changes.

Detonation proceeds as a wave traveling at high speed, from 4000 to 9000 ms^{-1} in various explosives, with a shock wave at the front of the wave structure. The compression in the shock heats the explosive enough to make it react rapidly. The energy released in the reaction supports the shock. The shock is supersonic, going as fast as the available energy can drive it, so nothing occurs ahead of the shock. In the reaction zone the flow is subsonic so energy can be transferred, but at the end of the reaction zone the flow becomes supersonic, and anything that happens in that supersonic flow cannot come forward to affect the reaction zone. It is for these reasons that the detonation is almost independent of the external conditions. Only at the edges can it be perturbed.

High explosives were discovered about the middle of the 19th century by chemists developing new dyes. Ascanio Sobrero, an Italian chemist, first prepared nitroglycerin and several other high explosives in 1846 and 1847. Alfred Nobel in 1864 developed a method of initiating nitroglycerin reliably by a fast compression wave, or shock wave, but it was dangerous to handle and ill-suited to mining operations. In 1867 Nobel was granted a patent for an explosive prepared by mixing nitroglycerin with a porous absorbent such as charcoal, diatomaceous earth, or fine sawdust. This explosive, called dynamite, proved to be just what was needed for the developing industrial revolution. In a few years it replaced black powder throughout the world. Many compositions competed with dynamite: a dictionary of explosives published in 1891 listed more than a thousand explosives.

After the middle of the 20th century, dynamite was replaced by explosives prepared from ammonium nitrate and fuel oil as granular mixtures, as slurries, or as emulsions. In the United States alone the annual use of high explosives is more than five billion pounds per year, or nearly 20 pounds for each person. A pound of explosive will break about 3000 pounds of rock, so about 60,000 pounds of rock is broken for each person in the United States each year. A large fraction of the explosive is employed to break the rock overburden of coal seams, other uses are in other mining, road construction, lumbering, and farming. Almost any product we purchase has had explosive used for it at some stage.

The first high-precision application of high explosives was to nuclear weapons, developed during World War II, where explosive was used for the precise dynamic assembly of the fissionable material. The nuclear weapons laboratories around the world have contributed to the detailed theory of detonation, to numerical modeling of detonations, to the development of powerful and safe explosives, and to the experimental techniques for studying explosives.

Nonlinear relations are especially important to detonation. The shock wave forms because the stress-strain behavior of the explosive is nonlinear. Materials be-

come stiffer as they are compressed, so the sound speed increases with pressure, and a compression wave steepens to become a shock. The extremely strong nonlinear dependence of the reaction rate on temperature is also very important. It is the on-off switch for the release of energy. For example, a typical rate law for an explosive might be $d\lambda/dt = k(1 - \lambda)e^{(-T^*/T)}$, where k is the limiting rate; λ is a progress variable for the reaction, going from zero to one as the explosive goes to products; t is the time; T is the temperature; and T^* is the activation temperature. If $k = 10^{20} \text{ s}^{-1}$ and $T^* = 25,000 \text{ K}$, the time required for half of the explosive to react when kept at constant temperature is 341 million years at 300 K (room temperature), 8.64 ms at 600 K, and 8.03 ns at 900 K.

Nuclear Weapons

In nuclear fission weapons, U^{235} or Pu^{239} is bombarded by neutrons that cause it to split into two lighter nuclei, releasing a large amount of energy and also emitting more neutrons. If more neutrons are generated than escape through the surface, the exponential increase in the number of neutrons leads to an explosion. A fusion weapon is initiated by a fission weapon and releases energy as hydrogen, deuterium, tritium, and lithium fuse to make heavier nuclei. These weapons release a million or more times as much energy as the same weight of conventional chemical explosive. The energy is often quoted in kilotons or megatons. These units are based on an assumed yield for TNT of 1000 cal g^{-1} or 4187 J g^{-1} . The metric tonne is 10^6 g and the kiloton is a thousand times that, so a kiloton is 10^{12} cal or $4.187 \times 10^{12} \text{ J}$, and a megaton is $4.187 \times 10^{15} \text{ J}$.

Asteroid Collision with Earth

About 65 million years ago an asteroid hit the earth leaving the crater Chicxulub in Yucatan, Mexico, and perturbing the conditions on earth to the extent that dinosaurs and many other animals and plants became extinct. The energy deposited was the kinetic energy of the asteroid. The exact details cannot be known, but if the asteroid was 12 km in diameter with density 2500 kg m^{-3} and relative speed 20 km s^{-1} , its kinetic energy was $4.5 \times 10^{23} \text{ J}$. An obvious time constant for the energy release is the diameter divided by the speed, 0.6 s. The kinetic energy divided by the time gives the power as $7.5 \times 10^{23} \text{ W}$; the actual value is a few times smaller.

An asteroid of the Chicxulub size is not slowed much by the Earth's atmosphere and reaches the Earth's surface. A smaller asteroid is slowed more, and the compression wave from the air travels through the asteroid. If the asteroid is small enough, the compression wave reaches the rear surface before the asteroid reaches the ground. The high pressure inside

the asteroid causes it to expand and break up into small pieces that are then slowed more by the air. The kinetic energy is transferred suddenly to the air, and there is an explosion above the surface of the earth. The Tunguska Event in Central Siberia in 1908 flattened trees over an area of about 2000 km^2 . It was caused by an asteroid about 60 m diameter that exploded about 8 km above the surface. Its kinetic energy was about $4 \times 10^{16} \text{ J}$.

Volcanoes

The 1883 eruption of the Indonesian volcano Krakatau, which blew ash to a height of 80 km and ejected 22 km^3 of rock, was heard in Australia 4600 km away. Tsunamis caused by the eruption reached heights of 40 m and killed 34,000 people.

Mount St. Helens, in the state of Washington, erupted in 1980 and has been studied extensively. It ejected 2.7 km^3 of rock, devastated an area of 550 km^2 , and blew down an estimated 10^7 trees.

A huge volcanic explosion occurred in Yellowstone, United States, about 2,000,000 years ago. About 3000 km^3 of rock were ejected. No explosion of such a magnitude has been experienced during the period of human civilization.

Novae and Supernovae

A nova occurs in a close binary star system made up of a red giant and a white dwarf. Hydrogen-rich matter from the red giant is pulled onto the surface of the white dwarf. When enough matter is accumulated, a nuclear fusion detonation occurs, causing the ejection of hot surface gases and resulting in an extraordinary increase in luminosity. A supernova occurs when a massive star exhausts its nuclear fuel and its core collapses to become a neutron star. The outer layers of the star are attracted by the gravitational pull of the core, and then rebound from it. A shock wave generated in the collision propagates outward and blows off the surface gases.

EXTREMUM PRINCIPLES

Extremum principles are ubiquitous in mathematics, with wide applications in areas ranging from genetic theory (Narain, 1993) to thermodynamics (Velasco & Fernandez-Pineda, 2002). The simplest sort of extremum principle occurs in differential geometry, whenever one considers a differentiable function $f(x_1, \dots, x_N)$ of N variables and wishes to determine the critical points of f , namely those x that satisfy

$$\nabla f(x) = 0.$$

The Hessian matrix H has entries given by the second derivatives

$$H_{jk} = \frac{\partial^2 f}{\partial x_j \partial x_k}(x)$$

(assuming these exist). If all the eigenvalues of the Hessian are positive (negative), then this ensures that x is a local minimum (maximum); eigenvalues of mixed sign correspond to a saddle point. The general characterization of functions in terms of their behavior near critical points is the subject of Morse theory (Morse & Cairns, 1969).

Probably the most widespread type of extremum principles are those arising from the application of the calculus of variations (Gel'fand & Fomin, 1963). One of the first historical examples of this sort is the brachistochrone problem posed by Johann Bernoulli the elder in 1696: given a particle sliding from rest along a path between two fixed points under the influence of gravity, find the plane curve such that the time taken is minimized. The solution curve (a cycloid) was obtained by both Johann and Jakob Bernoulli, and also by Newton, Leibniz, and l'Hôpital. Nowadays, the problem is usually solved directly through the use of the total time functional

$$T = \int_{x_0}^{x_1} \sqrt{\frac{1 + (y')^2}{2g(y_0 - y)}} dx \equiv \int_{x_0}^{x_1} F(y, y') dx, \quad (1)$$

$$y' = \frac{dy}{dx},$$

where $y(x)$ is the plane curve joining the points (x_0, y_0) and (x_1, y_1) and g is the acceleration due to gravity. To

minimize the time, it is necessary that the first variation of the functional T should vanish,

$$\delta T = 0,$$

which leads to the Euler–Lagrange equations

$$\frac{\partial F}{\partial y} - \frac{d}{dx} \left(\frac{\partial F}{\partial y'} \right) = 0 \quad (2)$$

The solution of (2) is given parametrically in terms of (x_0, y_0) and another constant h by

$$x(\theta) = x_0 + (\theta - \sin \theta)/(2h^2),$$

$$y(\theta) = y_0 - (1 - \cos \theta)/(2h^2).$$

In complete analogy to the Hessian condition in finite dimensions, the positivity of the second variation $\delta^2 T$ ensures that the cycloid yields a minimum of the functional $T[y]$.

In physics perhaps the most important extremum principle of all is the Principle of Least Action. An early proponent of this notion was Pierre Louis de Maupertuis, who employed an extremality argument to solve a problem in statics (Beeson, 1992). Maupertuis, who was tutored by Johann Bernoulli, was in regular correspondence with Leonhard Euler, and the work of the latter laid the foundation for the subsequent development of the subject. The enormous generality of the least-action principle became apparent from the Lagrangian formulation of classical mechanics (Goldstein, 1950), as derived from the action functional

$$S[\mathbf{q}] = \int_{t_0}^{t_1} L(\mathbf{q}, \dot{\mathbf{q}}, t) dt. \quad (3)$$

The variable t is the time, and the vector $\mathbf{q}$ and its time derivative $\dot{\mathbf{q}}$ denote the generalized coordinates and velocities, respectively. Requiring that the action should be stationary with respect to variations that vanish at the initial and final times, so

$$\delta S = 0, \quad \text{with } \delta \mathbf{q}(t_0) = 0 = \delta \mathbf{q}(t_1), \quad (4)$$

it follows (after an integration by parts) that L must satisfy the Euler–Lagrange equations

$$\frac{\partial L}{\partial \mathbf{q}} - \frac{d}{dt} \left(\frac{\partial L}{\partial \dot{\mathbf{q}}} \right) = 0.$$

The extremality condition (4) is truly fundamental, since once the Lagrangian L has been specified appropriately, then all the classical equations of motion for a mechanical system (in particular, Newton's Second Law) are a direct consequence. Even the geodesic equations for a Riemannian manifold arise in this way (Choquet-Bruhat, 1968), by taking the purely kinetic (free particle) Lagrangian

$$L(\mathbf{q}, \dot{\mathbf{q}}) = g_{jk}(\mathbf{q}) \dot{q}^j \dot{q}^k,$$

where g_{jk} is the metric tensor (the Einstein summation convention is assumed).

In parallel to the development of mechanics, a corresponding extremum principle was employed in optics, namely Fermat's Principle of Least Time. This is more correctly formulated within the theory of geometrical optics (Kline & Kay, 1965), as the requirement that the path taken by light traveling between two points P_1 and P_2 is such that the optical distance is *extremized*, that is,

$$\delta \int_{P_1}^{P_2} n(x, y, z) ds = 0, \quad (5)$$

where $n(x, y, z)$ is the refractive index at the point (x, y, z) in the medium and s denotes arc length along the path. Contrary to Fermat's original formulation, if the optical distance is extremal, then in general, the time taken for the light to travel between P_1 and P_2 need not be minimized—this only holds in certain special cases.

The precise analogy between geometrical optics and mechanics was fully appreciated and exploited by Hamilton. Choosing a parameter τ along the light path such that $\mathbf{q} = (x, y, z)^T$ satisfies

$$|\dot{\mathbf{q}}|^2 = n^2, \quad ds = |\dot{\mathbf{q}}| d\tau, \quad (6)$$

the equations arising from the variational principle (5) are just

$$\ddot{\mathbf{q}} = \nabla \left(\frac{1}{2} n^2 \right), \quad n = n(\mathbf{q}),$$

which are equivalent to Newton's equations for a particle of unit mass moving in a potential $-\frac{1}{2}n^2$. In this mechanical analogy, τ should be reinterpreted as the time, while the first equation (6) implies that the total energy of the particle is zero.

The Principle of Least Action is also essential in field theory. A scalar field theory in N dimensions has the action

$$S[\phi] = \int_V \mathcal{L}(\phi, \phi_\mu, \dots) d^N x$$

with the Lagrangian density $\mathcal{L}$ being a function of the field ϕ , its first derivatives ϕ_μ ($\mu = 1, \dots, N$), and possibly higher derivatives. The appropriate variational principle for the classical field equations is

$$\delta S = 0 \quad \text{with } \delta \phi(x) = 0 \quad \text{for } x \in \partial V,$$

so that the variations vanish on the boundary of the space-time volume V . In the path integral formalism of quantum field theory, as pioneered by Richard Feynman (Feynman & Hibbs, 1965), the central object is the

partition function, defined in terms of the action by

$$Z = \int e^{iS[\phi]} \mathcal{D}\phi,$$

where $\mathcal{D}\phi$ = path integral measure. When the action is coupled to an external source, $S \rightarrow S + \int J(x)\phi(x) d^N x$, then the vacuum expectation values of the field operators are obtained by taking successive functional derivatives $\delta/\delta J$ of Z . This is the key technique for calculating Feynman rules and perturbative scattering amplitudes in gauge field theory (Bailin & Love, 1986).

Another sort of extremum principle appears in game theory (Owen, 1982). In the simplest case of two-person zero-sum games, with two players denoted “row” and “column” and strategies labelled by an index j ($j = 1, \dots, M$) for the row player and an index k ($k = 1, \dots, N$) for the column player, the payoffs to the row player form an $M \times N$ matrix $\mathcal{A}$. The matrix element $\mathcal{A}_{jk}$ is just the payoff to the row player arising from the pure strategy combination (j, k) ; since the game is zero-sum, the corresponding payoff to the column player is $-\mathcal{A}_{jk}$. If the maximum of the row minima in the payoff matrix is equal to the minimum of the column maxima, then this is a saddle point (or minimax point), corresponding to an optimum solution of the game. However, a saddle point does not exist in general, and so it is necessary to resort to mixed strategies, taking the set of probability distributions $S_X \times S_Y$ on the strategy space, where

$$S_X = \left\{ x \in \mathbb{R}^M \mid x_j \in [0, 1], \sum_{j=1}^M x_j = 1 \right\},$$

$$S_Y = \left\{ y \in \mathbb{R}^N \mid y_k \in [0, 1], \sum_{k=1}^N y_k = 1 \right\}.$$

Then the Minimax Theorem, due to John von Neumann (von Neumann & Morgenstern, 1947), states that

$$\max_{x \in S_X} \min_{y \in S_Y} x^T \mathcal{A} y = v = \min_{y \in S_Y} \max_{x \in S_X} x^T \mathcal{A} y. \quad (7)$$

The quantity v is the expected payoff to the row player corresponding to some optimal mixed strategy

combination (x, y) and is called the *value* of the game. The existence of a more general sort of equilibrium in n -person, noncooperative games has been proved by John Nash (1951). Nash's proof relies on properties of convex functions (as does the standard proof of the Minimax Theorem). Convex analysis has also been used recently in thermodynamics, for a general proof of the minimum energy principle, starting from the maximum entropy principle and using the concavity of the entropy (Prestipino & Giaquinta, 2003).

FAIRY RINGS OF MUSHROOMS

Much of the mythology and mysticism formerly associated with fairy rings is summed up by the words of Prospero in Shakespeare's *The Tempest*, V.i: "Ye elves of hills... that/ By moonshine do the green sour ringlets make,/ Whereof the ewe not bites, and you whose pastime/ Is to make midnight mushrooms..." However, in what could be interpreted as a minor triumph of reason over superstition, Prospero's invocation is not to the sorcery that was supposedly imbued in fairy rings, but a declaration that he is giving up magic forever.

Fairy rings are not caused by supernatural beings, witches, moles, snails mating, or lightning—these being some of the early explanations, all the more hilarious *now* for being propounded so seriously back *then*, for the annular rings of dead grass, fringed on both edges by concentric rings of over-lush grass, that are often evident in grassy fields. They are caused by fungi. One of the first scientific investigations to establish this fact was reported by Wollaston (1807), whose explanation of fairy rings is still broadly accepted today. Despite this demystification, their appeal to the human imagination remained strong. Kipling (1906) wrote *Puck of Pook's Hill*, a story in which magical manifestations occur when children perform *A Midsummer Night's Dream* in a fairy ring, and Conan Doyle in *The Coming of the Fairies* (1923) only reluctantly admitted that fairy rings were due to fungal growth.

The mode of life involving progressive radial increase from a central point is not unusual among fungi. As pointed out by Ramsbottom (1953), hundreds of fungi grow in circular patterns, including microscopic ones such as *Penicillium* molds as well as those with macroscopic fruiting bodies such as mushrooms and puff-balls. Although the conditions governing initiation of a ring are still obscure, many scientific studies have documented the kinetics of expansion, the species involved, and the biology

and ecology of fairy rings. Two excellent and complementary studies are reported in Shantz & Piemeisel (1917) and Dowson et al. (1989).

The underground body of a fairy ring fungus, consisting of a network of filaments called the mycelium, grows radially outwards as it consumes organic matter in the soil. Behind the fungus front, the mycelial mass dies, so that the advancing live fungus front is actually a strange sort of disconnected organism. The dead filaments form a dense and water-repellant mat. Grass in this advancing annular region dies, due simply to physiological drought. Inside this bare region, the grass can grow luxuriantly because the dead filaments eventually decay, providing nitrogen-rich fertilizer. In advance of the fungal front, the grass also grows dark and luxuriant because of the peculiar (to us) eating habits of fungi: they exude digestive enzymes into the medium, then absorb this pre-digested food. Left-over digested food stimulates the grass forward of the fungus.

The radial growth rate of grassland fairy rings has been measured between 99 and 350 mm/year (Dickinson, 1979) and diameters of tens and hundreds of meters have been recorded. The obvious but rather awesome conclusion is that fairy rings may be among the world's oldest living organisms, since many rings are estimated to be several centuries old and some are believed to be 600 or 700 years old. It would be a fascinating exercise to obtain supporting evidence, such as historical records or results from scientific dating methods, for the ages of large fairy rings.

At favorable times of the year, fruiting bodies—mushrooms or toadstools—may be put forth around the circumference of a fairy ring. In woodlands these are often the only obvious manifestation of a fairy ring, since leaf-litter usually covers the ground (Figure 1). Because they depend on the roots of a tree for nutrient supply, woodland fairy rings are referred to as "tethered" rings, whereas those in grassland, for which the nutrient source is spread though the ground, are called "free" rings. The growth of tethered rings is coupled to the radial growth of the host tree roots, and they tend to reach an equilibrium diameter, determined

Figure 1. A typical fairy ring in grass.

by the mature size of the tree, rather than increase indefinitely (Gregory, 1982).

What happens when two or more fairy rings meet? Usually, the putative intersecting portions of same-species rings are extinguished, because of direct competition for resources or as each reaches the other's annular dead zone where nutrients and moisture are depleted in any case. Rings of different species either continue growing through each other or only the dominant species may survive. Rings of different species may also form inside one another.

A simple mathematical model for the ecology of fairy ring systems was developed by Parker-Rhodes (1955), from which was derived estimates for the proportion of ground covered by rings at a given time, the age distribution of rings, and geometric factors affecting inter- and intra-specific competition, such as rate of birth of new rings per unit area and distance between their centers. This model was extended by Stevenson & Thompson (1976) to include boundary effects and a more realistic treatment of the rings as annuli rather than discs. Their conclusions had some interesting implications for the management and control of fairy rings.

Why would anyone want to control them? Some people, sadly, consider fairy rings to be a pathogenic nuisance, a disease to be eradicated; and it is true that they can spoil the appearance and functionality of lawns, golf courses, playing fields, and pastures. The modeling results of Stevenson & Thompson (1976) indicated that if one's aim is to control a population of harmful rings by using an antagonistic but innocuous species of rings, it is more effective in the long term to choose the *smallest* growth rate available. In their work, the rings' growth rate was assumed constant.

If we admit, however, that the growth rate is variable, then fairy rings must be modeled as a dynamical system, and since they spread in two spatial dimensions, the appropriate dynamical description is a system of partial differential equations. Davidson et al. (1997) modeled the spatiotemporal dynamics of fungal mycelia by nonlinear reaction-diffusion equations describing the coupled evolution of the mycelial biomass and nutrient substrate concentration. They found that qualitative

features of the development of fairy rings, such as the annular advancing front, degeneration of colony centers, and extinction of the interface between two colliding fronts, were reflected in the structure of solutions to the equations.

This type of predictive computational modeling and simulation of radial growth patterns is likely to become more important in future—and not only because it gives fairy rings the ultimate modern imprimatur and authority of the computer. Other organisms are known to exhibit the fairy ring habit of growth. In the semi-arid rangelands of Australia, for example, certain species of saltbush grow radially outwards from a central origin forming a slowly increasing ring of foliage, the interior of which is bare ground. The patterns on the landscape formed by these blue-gray saltbush rings on the red soil are very striking from the air. The saltbush is a nutritious food source for sheep; thus one might be interested in management strategies that *increase* the covering fraction of saltbush and in factors that affect its growth. In this and other similar problems, the results from mathematical modeling of fungus fairy rings will provide valuable insights.

FEEDBACK

Long before the invention of electrical amplifiers and generators, feedback was used widely in mechanical

control devices, including the governor that was devised by James Watt in 1784 to stabilize the speed of a steam engine. The theory of such a governor was developed in the latter half of the 19th century by James Clerk Maxwell and by Ivan Alekseevich Vyshnegradskiy. Although the results obtained by Maxwell and Vyshnegradskiy seem contradictory, they present complementary aspects of the analysis. We consider briefly the detailed discussion of these results as given by Neimark et al. (1985).

The Lagrange equations for a steam engine with a governor are

$$I(\vartheta)\ddot{\varphi} + I'_{\vartheta}(\vartheta)\dot{\varphi}\dot{\vartheta} = M_r(\varphi, \vartheta) - M_l, \\ I_g\ddot{\vartheta} - \frac{1}{2}I'_{\vartheta}(\vartheta)\dot{\varphi}^2 + U'_{\vartheta}(\vartheta) + h\dot{\vartheta}, \quad (1)$$

where $I(\vartheta)$ is the moment of inertia of the engine and governor about the engine shaft, φ is the rotation angle of the engine shaft, ϑ and I_g are, respectively, the angular deviation and the moment of inertia of the governor balls, $M_r(\varphi, \vartheta)$ is the driving torque, M_l is the moment of load, and $-U'_{\vartheta}(\vartheta)$ and $\dot{\vartheta}$ are, respectively, the moments of gravity and viscous friction.

For ideal functioning, Maxwell assumed that the friction factor h must be as small as possible and the governor sensitivity $d\vartheta_0/d\Omega$ (where $\Omega = \dot{\varphi}$, φ_0 and ϑ_0 are the equilibrium values of φ and ϑ) must be as large as possible, and he gave recommendations how these conditions could be fulfilled. Vyshnegradskiy, on the other hand, understood that the friction plays an important role by promoting the stability of control. Therefore, he proposed adding a new element to the governor, called the cataract. In addition, Vysnegradskiy showed that for stability of control $d\Omega/dM_l$ must be negative and constructed his famous diagram in the plane $d\Omega/dM_l$, Ih/I_g , now known as the Vysnegradskiy diagram. Maxwell's ideas have also been realized in practice by a device called an "isodromic" in which feedback is effected by a rod that changes its length due to stretching or compressive force.

In the context of electronic amplifier theory, a detailed mathematical treatment of linear feedback was given by Henrik Bode (1950). Here the basic formula is

$$G = \frac{A}{1 - \mu A}, \quad (2)$$

which was famously discovered by Harold Black in 1927 (Brittain & Black, 1997). In this equation, A is the (large) forward gain of an amplifier, μ is the loss of a passive feedback circuit, μA is the open-loop gain, and G is the closed-loop gain. Assuming the amplifier does not oscillate and making $\mu A \gg 1$ implies $G \approx 1/\mu$. Thus, the closed-loop gain is essentially determined by the properties of a passive circuit (μ), which is far less sensitive to variations in temperature and aging than the

Figure 1. The block diagram of the simplest self-oscillatory system with inertial excitation.

forward gain (A). Long-distance telephone service—which requires a large number of highly stable repeater amplifiers—was made possible by Black's invention.

To avoid low-frequency oscillations, the amplifier system of Equation (2) is designed with the open-loop gain having a phase shift of 180° at low frequencies, which corresponds to negative feedback. To avoid oscillations resulting from positive feedback at higher frequencies (where the phase shift approaches 360°), it is necessary and sufficient that the complex mapping of the frequency axis by the open-loop gain function does not surround the point $+1$ in the μA -plane—the Nyquist criterion (Bode, 1950).

Positive feedback reveals itself in the appearance of negative friction or negative resistance, whereas negative feedback causes the stabilization of device parameters. In Watt's governor, for example, negative feedback stabilizes the speed of rotation, and in other devices it can stabilize frequency variations, the gain factor, and so on. In certain systems, however, negative feedback can result in self-excitation of oscillations. Such systems were called "systems with inertial excitation" by Babitzky & Landa (1982, 1984), and they often arise in physical and engineering studies. The excitation of oscillations in such systems is conditioned by the so-called inertial interaction between dynamical variables occurring as a result of inertia in the feedback loop.

A block diagram of the simplest self-oscillatory system with inertial excitation is shown in Figure 1. The inertial interaction between dynamical variables, like negative friction, can be both linear and nonlinear. A linear interaction can, under certain conditions, lead to spontaneous oscillations, whereas a nonlinear interaction can result in the hard excitation of oscillations (requiring that a threshold be overcome).

A simple system with linear inertial interaction is

$$\ddot{x} + 2\delta\dot{x} + \omega_0^2 x = -ky + f(x, \dot{x}, y), \\ \dot{y} + \gamma y = ax + \varphi(x, \dot{x}, y), \quad (3)$$

where $f(x, \dot{x}, y)$ and $\varphi(x, \dot{x}, y)$ are nonlinear functions free from linear terms, and the parameter a is proportional to the gain of the amplifier. The inertia of the feedback loop is characterized by the parameter γ . The condition of self-excitation of oscillations can

be shown to be $\gamma \leq \gamma_{\text{cr}}$, where

$$\gamma_{\text{cr}} = -\delta + \sqrt{\delta^2 + ak/2\delta - \omega_0^2}.$$

Because γ_{cr} should be positive, self-excitation can occur only for $ak \geq 2\delta\omega_0^2$. The condition $\gamma \leq \gamma_{\text{cr}}$ signifies that the feedback loop must be sufficiently inertial (an inertia-less feedback loop corresponds to $\gamma \rightarrow \infty$).

Systems with inertial feedback need not be self-excited. A child on a swing, for example, is an inertial system that is not self-excited. Interestingly, the oscillation of a swing is often inaccurately presented in textbooks as an example of parametric excitation. If oscillations are excited by a child who stands on the swing and lifts her center of gravity up and down at the proper moments, the system is not parametrically excited, because the oscillation frequency of the center of gravity is not constant but tuned according to variations of the frequency of the oscillations of the swing. Thus, a child on a swing is a control system with feedback that is self-oscillatory but not self-excited. For excitation of self-oscillations some finite initial perturbation is necessary (i.e., the excitation of oscillations is hard).

The simplest equations describing oscillations of a swing are

$$\ddot{x} + 2\delta\dot{x} + \omega_0^2 x = -bxy, \quad \dot{y} + \gamma y = ax^2, \quad (4)$$

where the variable y describes the position of the child's center of gravity and γ is the inertial factor of the control circuit. If the feedback is slightly inertial (i.e., γ is too large to put $y \approx (a/\gamma)x^2$), then the variable x obeys the Duffing equation, which has no self-oscillatory solution. Self-oscillations exist only for modest values of γ , when the feedback loop is sufficiently inertial.

Examples of self-oscillatory systems with inertial excitation include the Lorenz system, the Helmholtz resonator with non-uniformly heated walls, a heated wire with a weight at its center, the Vallis model for nonlinear interaction between ocean and atmosphere, a modified Brusselator, an air-cushioned body, and a lumped model of the "singing" flame (Landa, 1996, 2001). Note that the mechanism of self-excitation of oscillations in some continuous system is similar to the examples considered above. Among these are the Rijke tube and a distributed model of the "singing" flame (Landa, 1996).

It must be emphasized that feedback can be nonlinear as well as linear. Although nonlinear feedback cannot cause self-excitation of oscillations, it is of primary importance in their development, and many examples are known. In addition to the swing, noted above, nonlinear feedback plays a role in population dynamics, and it is related to the development of turbulence in a subsonic submerged jet, where the feedback is realized via an acoustic wave. In general, positive feedback

plays a key role in the emergence of coherent structures (Landa, 1996).

FERMI ACCELERATION AND FERMI MAP

In a seminal paper, Enrico Fermi (1949) proposed two related methods of producing cosmic rays by accelerating charged particles by repeated collisions with moving magnetic fields. The particles could either be trapped by magnetic mirroring (See **Averaging methods**) or be deflected without trapping. In either case, the charged particles gain energy if the magnetic field is moving opposite to the particle's motion and lose energy if the motions are in the same direction. For random motions of the magnetic fields the net effect is stochastic acceleration; that is, the probability is higher for an accelerating collision, due to the relative velocities. The mechanism could explain the power law of proton energies and was consistent with the magnitude of the cosmic ray energies. However, because of the competition between energy loss due to ionization and energy gain from the stochastic heating, the process could not reasonably explain the existence of high mass cosmic rays. More recently, after the discovery of supernovas, and observing magnetic fields and motions of supernova remnants (SNRs), the trapping version of Fermi's acceleration mechanism has been closely examined. A general understanding, developed over the last few years, is that shock waves in SNRs can repeatedly accelerate trapped charged

particles to produce both proton and higher mass cosmic rays (see a recent account by Malkov et al. (2002), and references therein).

Well before the recent interest in cosmic ray production by SNRs, the original basic idea of Fermi acceleration was being investigated with simple models. In particular, the question was asked whether the nonlinear dynamics of the particle motion would lead to stochastic acceleration even if the particles were acted on by periodic forces. A simple mapping model to detect this effect is that of a ball bouncing between a fixed and an oscillating wall. The model, developed by Ulam in 1961, was very straightforward to implement on a computer. The results were explained analytically and confirmed numerically in work during the 1960s and early 1970s by, among others, Zaslavsky and Chirikov, Brahic, and Lieberman and Lichtenberg (see Lichtenberg & Lieberman, 1991). They showed that for smooth forcing functions, the phase plane divides up into three distinct regions with increasing ball velocity: (1) a low-velocity region in which all period 1 fixed points are unstable, leading to stochastic motion over almost the entire region; (2) an intermediate velocity region in which islands of stability, surrounding elliptic fixed points, are imbedded in a stochastic sea; and (3) a higher-velocity region in which bands of stochastic motion, near the separatrices of the island trajectories joining the hyperbolic fixed points, are isolated from each other by regular orbits. The existence of region (3), in which invariant curves span the entire range of phase, bounds the energy gain of the particle. If the forcing function is not sufficiently smooth, then region (3) does not exist, in agreement with the Kolmogorov–Arnol’d–Moser (KAM) theory.

Because the Fermi particle acceleration mechanism was one of the first considered for determining the regions of parameter space where KAM surfaces exist and is easily approximated by simple mappings for which numerical solutions are attainable for “long times,” it has become a bellweather problem in understanding the dynamics of nonlinear Hamiltonian systems with the equivalent of two degrees of freedom. Various versions both with analytic and non-analytic wall oscillation functions, and with physically moving walls or walls that just impart momentum, have been analyzed. The basic Ulam model, together with an interesting variant of it, is shown in Figure 1. The model in (a) is homologous to many physical problems (see below) and has therefore been of considerable importance. A simplified version of the model in (b) leads to the *standard map*.

A simplified form of the Ulam map can be constructed if the oscillating wall imparts momentum to the ball, according to the wall velocity, without the wall changing its position in space. The problem defined in this manner has many of the features of the more physical problem and can be analytically treated with

Figure 1. Fermi acceleration models. (a) Version in which a particle bounces between an oscillating wall and a fixed wall. (b) Version in which the particle returns to an oscillating wall under the action of a constant gravitational acceleration.

various wall-forcing functions. In this simplified form, the mapping is

$$\begin{aligned} u_{n+1} &= |u_n + f(\psi_n)|, \\ \psi_{n+1} &= \psi_n + \frac{2\pi M}{u_{n+1}}, \end{aligned} \tag{1}$$

where u is the velocity, normalized to the maximum wall velocity, and ψ is the phase of the oscillating wall at impact, with $2\pi M/u$ a conventionally used form for phase advance. Equation (1) is the product of two involutions and is, therefore area, preserving; that is, it satisfies the Jacobian condition

$$\frac{\partial(u_{n+1}, \psi_{n+1})}{\partial(u_n, \psi_n)} = 1. \tag{2}$$

The mapping in (1) serves as an approximation (with suitably defined variables) to many physical systems in which the transit time between kicks is inversely proportional to a velocity. The absolute-value signs correspond to the velocity reversal, at low velocities, $u < 1$ but have no effect on the region $u > 1$, which is the primary region of interest. The forcing function $f(\psi)$ is often a sinusoid in physical problems, but it may have other forms.

The basic method to analyze mapping models is to expand about a fixed point $u_{n+1} = u_n$, $\psi_{n+1} = \psi_n + 2\pi n$, and examine the linear stability. Alternatively, a local linearization of the phase advance equation about the phase-stable value of u linearizes the phase-advance equation but retains the nonlinearity in the forcing term. This expansion leads to the standard map, whose nonlinear stability properties have been extensively analyzed. These procedures have determined the basic phase-plane motion, as described above. A difference between the exact and simplified mappings, which should be noted, is that the canonical variables are different, leading to different variables in which an invariant distribution is uniform. For the simplified problem, a proper canonical set of variables is the ball velocity and phase just before the n th impact

with the moving wall. The normalized velocity u then has a uniform invariant distribution. A detailed theoretical and numerical study of various forms of the Fermi map can be found in Lichtenberg & Lieberman (1991, Chapters 3 and 4), where many of the original references can be found. The Fermi map together with the standard map has also led to extensive analysis of phase space diffusion and correlations, which can also be found in the above reference, Chapter 5.

Various elaborated forms of the Fermi map have been applied to a variety of problems. Two such mapping models are electron cyclotron resonance heating (ECRH) in magnetic mirrors (Lieberman & Lichtenberg, 1973) and radio-frequency heating in capacitively driven discharges (Goedde et al., 1988). Although these physical models are generally more complicated than that given in (1), much of the basic analysis is similar. In particular, the expansion around fixed points can be made to investigate linear stability, and nonlinear expansions can obtain the standard mapping from which the KAM barriers to heating can be obtained. Weak dissipation can also be included in models, but this results in a contracting phase space not discussed here (See **Chaotic Dynamics**).

Another variant of the basic mapping is one for which the sign in the phase advance equation changes at some value of the action. Such mappings naturally occur in the dynamics of particles in circular accelerators where the sign transition occurs with increasingly relativistic motion in two frequency cyclotron heating and is an underlying cause of the period 3 "catastrophe" of the standard map. When the phase advance equation changes sign, the stable and unstable fixed points exchange their ψ -values, and the phase space structure between these fixed points undergoes a change in topology called reconnection. For further discussion of this phenomenon and references to the original literature, see Lichtenberg & Lieberman (1991, Sections 3.3 and 5.5).

FERMI-PASTA-ULAM OSCILLATOR CHAIN

A closely examined model of a high-dimensional system comprises a number of masses constrained to move along a line, with a specified force law governing their interaction. In the early 1950s, Enrico Fermi, John Pasta, and Stan Ulam (FPU) (Fermi et al., 1955) numerically examined such a chain of coupled oscillators, with a Hamiltonian of the general form

$$H(p, q) = \sum_{k=1}^N \left[\frac{1}{2} p_k^2 + \frac{1}{2} (q_{k+1} - q_k)^2 + \frac{1}{3} \alpha (q_{k+1} - q_k)^3 + \frac{1}{4} \beta (q_{k+1} - q_k)^4 \right], \quad (1)$$

where each of N particles has unit mass and unit harmonic coupling constant and the end points are either fixed (vertical position $q_1 = q_{N+1} = 0$) or periodic ($q_{N+1} = q_1$). The parameters α, β represent the nonlinearity in the forces between the particles in the chain. In the original FPU numerical computations either α or β was set equal to zero, and fixed end points were used to correspond to a discretized nonlinear spring. Most subsequent work was done with $\alpha = 0$ and is known as the FPU- β model. The FPU- β model can be normalized so that the significant parameter is βE , where E is the total energy, $H(p, q) = E$.

The original idea of Fermi was that the nonlinearity of the springs would lead to mode mixing such that thermodynamic properties in the lattice could be studied. The original numerical work placed the initial energy in the lowest mode of the linearized system, which at low energy becomes a quasimode of the nonlinear system. The N independent normal modes Q_k of the harmonic system with fixed end point boundary conditions give

$$q_i = \sqrt{\frac{2}{N+1}} \sum_{k=1}^N Q_k \sin \left(\frac{ik\pi}{N+1} \right), \quad (2)$$

for which the amplitudes q_i of the mass points form a half-sine for the lowest mode and pick up an additional zero for each higher mode. The harmonic mode frequencies are

$$\omega_k = 2 \sin \left(\frac{\pi k}{2N+2} \right). \quad (3)$$

The original numerical study surprisingly showed recurrences, rather than a thermodynamic spreading of energy among the modes. Subsequent studies explained these recurrences as resulting from near resonances among various combinations of modes (Bivins et al., 1973). However, the question of whether the nonlinearity led to long-term mixing of the energy remained an open question.

Although the original question of whether the nonlinearity led to equipartition among the degrees of freedom went unanswered during the 1960s, the FPU- β system became rightly famous for having inspired the early development of soliton theory. Zabusky & Kruskal (1965) showed that a Taylor expansion to transform the FPU chain into a continuous differential equation resulted in the Korteweg-de Vries (KdV) or the modified Korteweg-de Vries (mKdV) equation, depending on whether the α or β term in (1) was retained. For the FPU- β chain (mKdV equation), we have

$$u_\tau + 12u^2u_\xi + u_{\xi\xi\xi} = 0, \quad (4)$$

where time and length variables have been rescaled by $\tau = h^3t/24$ and $\xi = x - ht$; subscripts τ, ξ denote differentiation with respect to that variable.

The periodic solutions of (4), stationary in the frame $\xi - c\tau$, may be obtained by integrating to give

$$\frac{1}{2}u_\xi^2 + u^4 - \frac{1}{2}cu^2 + A \equiv \frac{1}{2}u_\xi^2 + P(u) = 0, \quad (5)$$

where A is a constant of integration. Equation (5) is in the form of a one-degree-of-freedom Hamiltonian, which is therefore integrable. Solutions have been obtained in terms of the Jacobi elliptic functions (or cnoidal waves) $\text{cn}(\xi, q)$, with q (the modulus) taken as a parameter with $0 \leq q^2 < 1$. This formalism led to the observations of the stability properties of solitons, and more generally motivated the development of the inverse scattering technique (Gardner et al., 1967). However, the explanation that long-time recurrences were due to initial conditions that were superpositions of stable solitons was not a complete picture and was ultimately misleading.

An explanation for the mechanism leading to stochastic diffusion of energy over the $2N$ -dimensional phase space, which also predicted a transition from regular to stochastic motion with increasing energy, was put forward by Izrailev & Chirikov (1966). Using the transformation to modes as in (2), they postulated that if the interaction of pairs of neighboring modes was sufficient to create overlapping beat modes, then the overlap would create global stochasticity. The concept that had been developed by Chirikov for low degree-of-freedom Hamiltonian systems, known as the Chirikov overlap criterion, was applied to the high-dimensional system by isolating a few modes containing the energy. The criterion had been confirmed numerically and later studied in great detail using the

standard map. The criterion can be shown to be roughly equivalent to requiring that the nonlinear frequency shift with the energy in a single mode be equal to the mode separation (Lichtenberg & Lieberman, 1991, Section 6.5b). Substituting (2) into (1), the nonlinear shift in mode frequency of mode k can be calculated approximately as $\Delta\omega_k \simeq 3\beta E_k \omega_k / 4N$. From (3), the frequency separation between low-frequency modes with $\omega_k \simeq \pi k / N$, $k \ll N$, is $\delta\omega_k \simeq \pi / N$, such that for overlap ($\Delta\omega_k / \delta\omega_k \geq 1$)

$$\beta E_k / N \geq 4/3k. \quad (6)$$

Stochastic energy transfer among modes, leading to approximate equipartition among modes, has been numerically found at much lower values of energy density than given by (6). Numerical studies of equipartition (e.g., Livi et al. (1985); Pettini & Landolfi, 1990) found that (6) roughly corresponds to a transition between an inverse time to obtain some measure of equipartition that scales as $\tau^{-1} \propto (E/N)^2$ at low energy, to a time scaling as $\tau^{-1} \propto (E/N)^{2/3}$ at high energy. The latter scaling models a random process that is very strongly stochastic. Furthermore, the prediction that mode overlap determines the transition between regular motion and stochastic diffusion leading to equipartition does not hold if the energy is initially placed in one or a few high-frequency modes. There is local mode mixing, but the high-frequency modes interact only weakly with the low frequencies, as theoretically predicted by Benettin et al. (1987), such that equipartition is not observed above the mode overlap transition on a fast time scale.

The mKdV soliton was found to become unstable from a low-frequency mode, leading to exponential growth of higher frequencies, which correspond quite closely to similar growth of higher frequencies in an oscillator chain (Driscoll & O'Neil, 1976). However, this low-frequency instability is neither a necessary nor sufficient condition for a transition to equipartition, as the soliton theory does not describe the high-frequency modes, but it does present a physical picture of the process that can hold a low-frequency mode together in the absence of coupling to high-frequency modes and how it can break down.

A more coherent picture of the underlying processes leading to equipartition has been developed recently. Basic phase space arguments indicate that, for relatively high-dimensional systems with not too small a perturbation strength, the probability will be high that a generic initial condition will lie in a stochastic portion of the phase space. Arnold diffusion will then transport energy over most of the degrees of freedom, essentially leading to equipartition, on some time scale. However, the time to equipartition can be exponentially slow.

Focusing on the region of weaker stochasticity, a transition was numerically found between power law and exponentially long time scales as the energy

density $\varepsilon = E/N$ of the system is decreased. This latter transition is of prime importance for the observation of equipartition, as it essentially separates observable times from those that are not observable. For the FPU chain, the main mechanisms leading to equipartition in this lower energy regime are that resonant interaction of some set of low-frequency modes, in which a significant portion of the energy resides, can lead to local superperiod (very low frequency) beat oscillations that are stochastic. The beat oscillations, which increase with energy, can become comparable to frequency differences between high-frequency modes. This results in Arnol'd diffusion transferring energy to high-frequency modes, on a power law time scale (DeLuca et al., 1995). Furthermore, the appearance of stochasticity corresponds to the onset of the mKdV instability. The driving frequency for diffusion is associated with the libration frequency of the resonance, Ω_B . Using resonant normal form perturbation theory to isolate the most important coupling to the high-frequency modes, the energy transfer to high-frequency modes by Arnol'd diffusion, depends exponentially on the frequency ratio as

$$\frac{dE}{dt} \propto \exp(-\pi\delta\omega_h/2\Omega_B), \quad (7)$$

where $\delta\omega_h$ is the difference frequency between two high-frequency modes. When $\Omega_B \sim \delta\omega_h$, the exponential factor is of order unity, allowing strong diffusion of energy to high-frequency modes, and equipartition on computationally observable time scales. In a separate work, an estimate of the scaling, with energy density, of the equipartition time for $E \gg E_c$ was found theoretically to be $T_{eq} \propto (N/E)^3$, which agrees with numerical computations (De Luca et al., 1999). The somewhat weaker quadratic scaling found in earlier work, as quoted above, was probably due to the use of a less accurate measure of equipartition.

If the energy is initially placed in high-frequency modes, the equipartition process is significantly different from that starting from low-frequency initial conditions. In this case, the dynamics is transiently mediated by the formation of unstable nonlinear structures. First, there is an initial fast stage in which the mode breaks up into a number of breather-like structures. Second, on a slower time scale, these structures coalesce into one large unstable structure. These structures have been called chaotic breathers (CB). Because a single large CB closely approximates a stable breather, the final decay stage, toward equipartition, can be very slow. This behavior has been observed in oscillator chains approximating the Klein-Gordon equation with various force laws and the FPU- β model (Cretegy et al., 1998; Mirnov et al., 2001). In Cretegy et al. (1998), the energy was placed in the highest frequency mode with strict

alternation of the amplitudes from one oscillator to the next (periodic boundary conditions). This configuration is stable up to a particular energy, for which there exist exact discrete solutions. Beyond this energy a parametric instability occurs, leading to the events described above. However, the nonlinear evolution does not depend on special initial conditions but will generically evolve from any high-frequency mode initial condition that has predominantly the alternating amplitude symmetry. One does not know, in this generic situation, whether there exists any true energy threshold. As discussed with respect to low-frequency mode initial conditions, the practical thresholds refer to observable time scales. From a phase space perspective, it is intuitively reasonable that for a large number of oscillators and not too low an initial energy, the generic set of initial conditions will lie in a chaotic layer, but the chaotic motion can remain close to a regular orbit for very long times (Lichtenberg & Lieberman, 1991).

Considerable insight into the behavior of a nonlinear oscillator chain, starting from high-frequency mode initial conditions, can be obtained by introducing an envelope function for the displacements of the oscillators. Low-order expansions produce PDEs that have integrable solutions in the form of envelope solitons, analogous to the solitons produced from low-frequency initial conditions (Kosevich, 1993). Higher-order terms usually destroy the integrability.

Substituting the envelope function $\psi_i(t) = (-1)^i q_i(t)$ in (1) (with $\alpha = 0$), using the continuous variable $x = ai$, a Taylor's expansion in a , the lattice period, yields

$$\begin{aligned} \psi_{tt} + 4\psi + 16\beta\psi^3 \\ + a^2\{\psi_{xx} + \beta(12\psi\psi_x^2 + 12\psi^2\psi_{xx})\} \\ + a^4\{(1/12)\psi_{xxxx} + \beta(3\psi_x^2\psi_{xx} + 3\psi\psi_{xx}^2 \\ + 4\psi\psi_x\psi_{xxx} + \psi^2\psi_{xxxx})\} + \dots = 0. \end{aligned} \quad (8)$$

Comparing (8) with (4) qualitatively explains why relaxation is accompanied by the formation of sharply localized states if energy is initially deposited in the high-frequency part of the spectrum where the effect of dispersion is small, while only broad nonlinear structures are formed if the energy is initially in the low-frequency modes where the dispersion is large. Using a dimensionless variable, introducing the rotating wave approximation (RWA) $\cos^3 \omega t \simeq (\frac{3}{4}) \cos \omega t$ and neglecting terms proportional to a^4 and higher, (8) can be integrated to yield

$$(-\omega^2 + 4)\psi^2 + \psi_x^2 + \beta(6\psi^4 + 9\psi^2\psi_x^2) = C_1, \quad (9)$$

which has integrable trajectories in phase space similar to (5) but includes a high-frequency drive ω . Depending on the boundary conditions, these phase trajectories represent multiple or single breathers.

As with low-frequency initial conditions, the soliton solution of the envelope, obtained from (9), becomes unstable with increasing energy. For most numerical studies of oscillator chains, the initial state imposed on the system is mainly that of a single linear mode. This state is generally not close to an equilibrium. The initial state rapidly relaxes, governed by the nonlinear equations. Numerical studies indicate that the chaotic breathers that are formed in the nonlinear processes are probably marginally stable, which accounts for their long-lived existence.

After a set of chaotic breathers has been formed, on a short time scale by a modulational instability or breakup relaxation, the breathers coalesce, on a longer time scale into a single chaotic breather. This process has been well documented numerically (Cretegnny et al., 1998; Mirmov et al., 2001) and an analytic estimate of the process made (Kosevich & Lepri, 2000; Mirmov et al., 2001) with the breather coalescence time found to scale as $\tau_B^{-1} \propto E_B/N$, the breather energy density. The background mode spectrum beats with the breather to transfer energy to low-frequency modes, resulting in equipartition on a slower time-scale as $T_{eq} \propto (E/N)^{-2}$ (Mirmov et al., 2001).

Although we have concentrated on the seminal problem of the FPU- β lattice, the results are qualitatively connected to other types of oscillator chains. For example, if the cubic, rather than the quartic, potential is retained in (1), then the Hamiltonian is equivalent to the lowest-order nonlinear expansion of the integrable Toda lattice. Consequently, the chain is considerably more stable. Other interesting types of lattices are composed of discretizations of Klein-Gordon equations. In particular, with a quartic potential, the dynamics of the Klein-Gordon Hamiltonian

$$H = \sum_{i=1}^N \left[\frac{1}{2} p_i^2 + \frac{1}{2} (q_{i+1} - q_i)^2 + \frac{1}{2} m^2 q_i^2 + \frac{1}{4} \beta q_i^4 \right], \quad (10)$$

has been compared with the FPU- β chain, showing both similarities and differences (Pettini & Cerruti-Sola, 1991). The stability of "discrete breathers" has also been examined for various chains (Cretegnny et al., 1998).

FERROMAGNETISM AND FERROELECTRICITY

Iron, nickel, cobalt, and some rare earths (e.g., gadolinium) are characterized by long-range ferromagnetic order. This originates at the atomic level and causes the unpaired electron spins to line up parallel to each other within a region of space called a magnetic domain. Domains range from 0.1 mm to a few mm in size. Within each domain, the net magnetization is large and homogenous, but over the entire sample it averages out to zero due to random orientations of spins. An externally applied magnetic field can cause the material to become macroscopically magnetized, as the magnetic

domains already aligned in the direction of this field grow at the expense of their neighbors and those neighbors reorient their magnetizations towards the field direction.

Ferromagnets have very high magnetic susceptibilities (χ), ranging from 1000 up to 100,000 (meaning the ferromagnet is that much easier to magnetize than free space), and they tend to stay magnetized following the application of an external magnetic field. This tendency to remember magnetic history is called "hysteresis." All ferromagnets have a maximum temperature, called the Curie temperature (T_C), which for iron is about 1043 K. Above T_C the ferromagnetic phase changes into a paramagnetic phase, in which induced magnetism is proportional to the applied field. Ferromagnets also respond mechanically to an applied magnetic field, changing length slightly in the direction of the applied field, a property that is called magnetostriction.

In addition to ferromagnets, there exist other magnetically ordered compounds with parallel-oriented sublattices. The simplest such example is antiferromagnetism with two antiparallel sublattice magnetizations. To measure the degree of order in a complex magnetic phase, as many order-parameter components as there are distinct sublattices may be needed. For ferromagnets, the order parameter is the net magnetization. In antiferromagnets, the order parameter is the staggered magnetization: $M_1 - M_2$, where M_1 and M_2 are the magnetization vectors for the two sublattices.

In 1907, Pierre Weiss proposed a phenomenological theory of ferromagnetism, building on the model of paramagnetism that Paul Langevin introduced in 1905. The Langevin function: $L = \coth(x) - 1/x$ (where $x = \mu H/kT$) describes the paramagnetic susceptibility of N non-interacting classical spins in a magnetic field of intensity H . Weiss assumed that spins interact with each other through a molecular field proportional to the average magnetization in the sample. So that

$$H_{\text{eff}} = H + \lambda M. \quad (1)$$

By replacing spin-spin interactions with the interaction of a single spin (S) and all its neighbors taken as an average field, the nonlinear problem was approximately solved giving rise to ferromagnetism for T below $T_C = \lambda C$, where

$$C = \frac{N\mu^2 S(S+1)}{3k} \quad (2)$$

with k denoting the Boltzmann constant.

As a consequence, the Langevin expression for susceptibility in paramagnetism

$$\chi = \frac{M}{H} = \frac{C}{T} \quad (3)$$

becomes the Curie-Weiss relation

$$\chi = \frac{C}{T - T_C} \quad (4)$$

above T_C , with spontaneous magnetization below T_C for ferromagnets. This is characteristic of a second-order phase transition. Spin alignment stems from the exchange interactions between spins whose energy can be expressed via the Ising Hamiltonian $\mathcal{H}$ in the case of strong uniaxial anisotropy favoring alignment parallel or antiparallel to the z -axis of quantization depending on the sign of the exchange constant J :

$$\mathcal{H} = - \sum_{i,j} J S_i^z S_j^z, \quad (5)$$

where S_i^z and S_j^z are the z -components of the spin vectors at the lattice sites i and j , respectively. In the absence of anisotropy, one uses the Heisenberg Hamiltonian that couples the spin vectors in a scalar product. Free-energy expansion of the Landau type can be obtained within the Curie-Weiss approximation for a Hamiltonian that includes the Zeeman interaction with an external magnetic field and an Ising-type spin-spin interaction.

Ferroelectricity was discovered in the beginning of the 20th century as a property of ionic, covalent, molecular crystals, and even polymers that possess electrical polarization either spontaneously (e.g., Rochelle salt) or under mechanical stress (piezoelectricity) or temperature changes (pyroelectricity). The net polarization of a ferroelectric crystal can be reoriented by applying an electric field. In ferroelectric phase transitions, a change in the crystal structure is accompanied by the appearance of spontaneous polarization. Ferroelectric phase transitions can be either displacive or order-disorder type. In displacive transitions (e.g., BaTiO_3), atoms or molecules exhibit small (compared with the unit cell) positional shifts with long-range correlations. These transitions are caused by phonons and the order parameter is the amplitude of the related lattice distortion giving rise to a change of the lattice structure. Displacive transitions are described using a continuous Landau-Ginzburg model with ensuing solitary waves. In order-disorder transitions (e.g., NaNO_2), atoms or molecules order themselves on distances comparable to the unit cell. A transformation between randomly distributed atomic positions of their local double-well potential bottoms ($T > T_C$) and an ordered arrangement ($T < T_C$) takes place. Models of order-disorder transitions use the Ising Hamiltonian with an effective (not real) spin variable.

Ferroelectric phase transitions involve symmetry changes in the crystal structure that are manifested by the emergence of an order parameter: spontaneous polarization vector P . For second-order transitions, the symmetry group of the ferroelectric phase is a

subgroup of that in the paraelectric phase (in which P is proportional to the applied electric field E). In some cases, such as the onset of ferroelectricity with a transverse optical branch, a so-called soft mode is responsible for the transition. The soft-mode's frequency ω_k for the wave vector k tends to 0 as $T \rightarrow T_c$. A special type of ferroelectric phase transition involves incommensurate phases where spontaneous polarization develops a spatial modulation with a wavelength that is incommensurate with lattice periodicity. The occurrence of incommensurate phases is usually explained by competition between long- and short-range forces, for example, in the Frenkel-Kontorova model. As in ferromagnets, ferroelectrics develop domains in which a particular orientation of polarization is selected. These domains can range in sizes from submicroscopic to macroscopic, and the region between two neighboring domains is called a domain wall.

FIBONACCI SERIES

Leonardo of Pisa (approx. 1175 to around 1250), also known as Leonardo Pisano, referred to himself as Fibonacci (or son of Bonacci), the name by which he is usually called today. As the son of a customs officer, he had opportunities to travel around the Mediterranean coast and observe many commercial practices. He saw that the Hindu-Arabic system of ten digits and its algorithms for arithmetic had many advantages over Roman numerals. His book of 1202 (revised 1228), *Liber Abaci*, meaning *The Book of the Abacus* or *The Book of Reckoning*, described the system in the

Italian vernacular, and so the decimal system became common in Europe.

In his book are some problems and puzzles that were meant as arithmetic practice using the new system. One referred to a problem about rabbits in a field: "A certain man put a pair of rabbits in a place surrounded on all sides by a wall. How many pairs of rabbits can be produced from that pair in a year if it is supposed that every month each pair begets a new pair, which from the second month on becomes productive?" It is based on the assumption that the pairs mate according to the same conditions. Each month, the number of rabbit pairs in the field is 1, 1, 2, 3, 5, 8, 13, 21, 34, 55, 89, 144. So the answer is 144 pairs after 12 months. The number of rabbits in any month is found by adding the number of rabbits alive in the last month (since we assume none die or are eaten) and adding to it the number of new rabbits born that month, which is one for each pair that was alive in the month before that. The rule is therefore "add the last two numbers to get the next." The next number in the series is 89 plus 144, or 255. The series was probably known before this and Fibonacci merely copied it from another source. The sequence is now called the Fibonacci sequence in his honor, but this name was not given until the late 1800s when Edouard Lucas rediscovered the series and wrote about some of its many properties.

Earlier than this, it had been noticed that the Fibonacci numbers (though not called that) appear in the number of petals of flowers of many plant species, in the arrangements of leaves round a branch, or seed whorls on a seed head. The study of such features of plants is termed phyllotaxis. There are flowers with 3 petals (clover) and many with 5, but none with 7 or 9 leaves or petals. The numbers 4, 6, and 10 also occur but the arrangement is of two sets of 2, 3, or 5. No scientific justification for this was given until Douady and Couder wrote about it in 1993 where they showed that if the growing tip of a plant (the meristem) produces a new primordial cell that becomes a leaf or petal or branch, then the optimal arrangement is for the new cell to be produced at the rate of 1.618 per turn of the growing point. This produces the least overlapping for leaves and the maximum exposure to collect sunlight, or for seeds, it provides the most compact packing (given the simple method of growth of the meristem) with even packing of seeds no matter how large the seed head becomes.

This number, precisely computed as $g \equiv (\sqrt{5} + 1)/2 = 1.6180339887 \dots$, is a famous number in geometry called the golden section (also golden ratio, golden mean, divine proportion). It appears as the ratio of diagonals to sides in a pentagon. The golden section as a decimal number never recurs, and so cannot be expressed exactly as a fraction (i.e., it is irrational). It has the property that its reciprocal (1 divided by the golden section) is 0.6180339887... This is

exactly 1 less than the golden section itself, giving rise to the definition of the golden section as “the positive number that is 1 less than its reciprocal.” In other words, $1/g = g - 1$ or $1 = g^2 - g$, a quadratic equation that is solved by the value above together with $-1/g = -0.6180339887 \dots$

The fractions that best approximate g are the ratios of two successive Fibonacci numbers: $3/2$, $5/3$, $8/5$, $13/8$, $21/13$ in the sense that no fraction with numbers smaller than the numerator of one of these terms will give a better approximation. It is this that explains why the Fibonacci numbers appear in phyllotaxis since the optimal arrangements are best approximated using Fibonacci numbers (or, indeed any series where the last two numbers are added to produce the next).

Since the Fibonacci rule is so simple, it is also found in other mathematical situations. For instance, suppose that houses can be made in two sizes, single (separate) and double (two attached), the latter taking twice the frontage along a road as the single ones. Given a road that is long enough for n houses on one side, how many arrangements are there that the architect can choose from? For instance, a road that can have 3 houses on it could have 3 singles, or else a double followed by a single or a single first and then a double—3 ways. For 4 houses there are 5 arrangements; for 5 houses, 8 possibilities. The number of arrangements is always a Fibonacci number.

The rule also applies to the family tree of a male honeybee. Male bees are produced from unfertilized eggs and female bees from fertilized eggs. So males have one parent and females have two. A male bee thus has one parent (F) and two grandparents (M and F), three great-grandparents and so on with 5, 8, 13, 21 as we go back each generation.

In two dimensions, a rectangle with sides in the golden ratio is called a golden rectangle. It has been observed in the shape of many parts of the Parthenon on the Acropolis in Athens, although none of the original plans of the building are extant. The Greeks knew of the ratio, and Euclid's *Elements* shows how to find and construct the golden section point on any line.

FIBRILLATION

See **Cardiac arrhythmias and electrocardiogram**

FILAMENTATION

When we look at a window on rainy days, we may observe a curious phenomenon: the rain forms a sheet of water on the glass. A single drop—from time to time—introduces a perturbation on this surface that is sufficient to trigger small-scale channels breaking the layer of liquid and escaping from it. Filamentary structures of water emerge from the unstable flow, destroying the initial expanse. The water sheet has thus decayed into filaments through an instability that is called filamentation.

Filamentation also occurs in plasma physics and nonlinear optics. In this context, an intense optical beam propagating in a focusing (Kerr) medium may break up into several spots due to the small inhomogeneities affecting its initial distribution, as evidenced by self-focusing experiments in solids, liquids, and gases (see, e.g., Bespalov & Talanov, 1966; Campillo et al., 1973). This phenomenon can be understood from the equation for the paraxial self-focusing of optical beams that describes the propagation of the slowly varying complex envelope ψ of a scalar electric field with central frequency ω_0 through a nonlinear medium. The envelope ψ , expressed in the frame moving with the group velocity, obeys the nonlinear Schrödinger (NLS) equation

$$i\partial_z \psi + \nabla_\perp^2 \psi + f(|\psi|^2)\psi = 0, \quad (1)$$

where $\nabla_\perp^2 \equiv \partial_x^2 + \partial_y^2$ represents wave diffraction and $f(|\psi|^2)$ models the nonlinear response of the medium. Here, the radial (x, y) and longitudinal (z) variables are normalized with respect to the beam waist w_0 and to the Rayleigh length $z_0 = \pi w_0^2 / \lambda_0$, depending on the linear refractive index n_0 and central wavelength λ_0 .

For an unsaturated Kerr medium, $f(s) = s$ and solutions of Equation (1) collapse at finite distance whenever their power $P = \int |\psi|^2 d\mathbf{r}$ exceeds the threshold $P_c \simeq 11.7$. Nonlinear responses of optical materials are, however, generally saturating, for example,

like $f(s) = s/(1 + \beta s)$ with $\beta = |\psi|_{\max}^{-2} \ll 1$. Such saturations occur in two-level systems, such as sodium and rubidium atomic vapors (Soto-Crespo et al., 1992).

Modeling filament formation requires a perturbation theory, following which small fluctuations break up steady-state solutions, expressed as $\psi_s(r, z) = \phi(r)e^{i\lambda z}$, where ϕ satisfies the differential equation

$$-\lambda\phi + \nabla_{\perp}^2\phi + f(\phi^2)\phi = 0 \quad (2)$$

and $\lambda = \text{const}$. Stability of ϕ can thus be investigated from the perturbed solution

$$\psi(x, y, z) = [\phi(x, y, \lambda) + \varepsilon\{v(x, y, z) + iw(x, y, z)\}]e^{i\lambda z}, \quad (3)$$

where v and w are real-valued functions with amplitude parameter $\varepsilon \ll 1$.

Linearizing Equation (1) with respect to these functions yields the eigenvalue problem

$$\partial_z v = L_0 w, \quad -\partial_z w = L_1 v, \quad (4)$$

where L_0 and L_1 represent the self-adjoint operators

$$\begin{aligned} L_0 &= \lambda - \nabla_{\perp}^2 - f(\phi^2), \\ L_1 &= \lambda - \nabla_{\perp}^2 - [f(\phi^2) + 2f'(\phi^2)\phi^2], \end{aligned} \quad (5)$$

with $f'(\phi^2) = \partial f(u)/\partial u|_{u=\phi^2}$. Combining Equations (4), we then obtain $\partial_z^2 v = -L_0 L_1 v$, and different filamentation-like instabilities may be investigated from this general formalism.

• **Modulational instability (MI):** Originally, Bespalov & Talanov (1966) proposed a modulational instability theory, following which oscillatory perturbations with an exponential growth rate split the beam envelope taken as a background uniform solution into small-scale cells. Perturbative modes are chosen as $v, w \sim \cos(k_x x) \cos(k_y y) e^{\gamma z}$, and they apply to a plane wave ϕ which, by definition, satisfies $\nabla_{\perp}^2 \phi = 0$, so that $\lambda = f(\phi^2)$. The growth rate γ is then given by Equation (4):

$$\begin{aligned} \gamma^2 &= k^2[2A - k^2], \quad A \equiv u f'(u)|_{u=\phi^2}, \\ k^2 &= k_x^2 + k_y^2. \end{aligned} \quad (6)$$

Plane waves are unstable with $\gamma^2 > 0$ in the range $0 < k < \sqrt{2A}$ and the maximum growth rate $\gamma_{\max} = A$ is attained for $k = k_{\max} = \sqrt{A}$. This instability promotes the beam breakup into a wave-train of small-scale filaments regularly distributed in the diffraction plane with the transversal spacing $\lambda_{\text{mod}} \simeq 2\pi/k_{\max}$ and longitudinal length $\sim \gamma^{-1}$. In practical uses, the number of filaments is close to the ratio $P_{\text{in}}/P_{\text{fil}}$, where P_{in} is the power of the input beam and P_{fil} the power enclosed in one filament. Considering each filament with radial symmetry, the evaluation $P_{\text{fil}} \simeq 2\pi \int_0^{\lambda_{\text{mod}}/2} r|\phi|^2 dr \simeq 2.65 P_c$ holds for unsaturated Kerr media [$f(s) = s$].

• **Filamentation on a ring:** For broad beams, self-focusing often takes place as a regular distribution of dots superimposed upon ring-like diffraction patterns, so that filamentation may not develop over the entire surface of the input beam. To model this instability, the Laplacian in Equation (1) can be rewritten as $\nabla_{\perp}^2 = r^{-1} \partial_r r \partial_r + r^{-2} \partial_{\theta}^2$, where θ denotes the azimuthal angle. Unstable modes $v, w \sim \cos(m\theta) e^{\gamma m z}$ with azimuthal index number m break up a spatial ring, which is modeled by a uniform background solution ϕ lying on a circular path with length $s = \bar{r}\theta$, where $\bar{r}$ is the mean radius of the ring. Equation (4) then yields (Soto-Crespo et al., 1992)

$$\gamma_m^2 = \left(\frac{m}{\bar{r}}\right)^2 \left(2A - \frac{m^2}{\bar{r}^2}\right) \quad (7)$$

and the maximum number of modulations on the ring is provided by the integer part number $m_{\max} = \text{int}\{\bar{r}^2 A\}^{1/2}$. An example of filamentation on a ring-diffraction pattern emerging from a tenth-order super-Gaussian beam is shown in Figure 1 for $f(s) = s$ in the presence of a random-phase noise. About seven to eight filaments emerge and rapidly collapse.

• **Transverse instability:** Although elementary, MI theory has been considered as the starting point for understanding laser filamentation, until plane waves are replaced by bounded solutions. These can be the soliton modes of the NLS equation, and the resulting instability is termed transverse instability. It appears when a soliton ϕ is perturbed by oscillatory modulations developing along one axis. For instance, when the Laplacian reduces to the 1-dimensional operator $\nabla_{\perp}^2 = \partial_x^2$ in Equation (2), a soliton solution $\phi(x, \lambda) = \sqrt{2\lambda} \text{sech}(\sqrt{\lambda}x)$ can undergo perturbative modes v, w decomposed as $V(x), W(x) \cos(k_y y) e^{\gamma z}$. These perturbations are local in x and they promote the formation of bunches, periodically distributed over the y -axis. The operators L_0 and L_1 in Equation (5) are transformed as $L_0 = \lambda - \partial_x^2 - f(\phi^2) + k_y^2$ and $L_1 = L_0 - 2f'(\phi^2)\phi^2$. For the cubic nonlinearity ($f(s) = s$), the instability growth rate is close to the theoretical curve $\gamma^2 = 1.08k_y^2(3\lambda - k_y^2)$ (Rypdal & Rasmussen, 1989). The same reasoning holds when the Laplacian of Equation (1) includes a third dimension, for example, a time variable, along which 2-dimensional spatial solitons are subject to periodic fluctuations. Because bounded solutions ϕ are not always accessible analytically, numerical computations are often required for determining γ^2 (Akhmediev et al., 1992).

Besides filament formation, Equations (4) and (5) provide information on the inner stability of solitons, known as orbital stability, which refers to the ability

Figure 1. Filamentation pattern numerically computed for a tenth-order super-Gaussian beam with $P_{\text{in}} = 30P_C$ in a cubic medium.

of initial solutions near equilibrium states to converge to robust soliton shapes. Standard procedures allow the stability criterion $dP(\phi)/d\lambda > 0$ to be established, where $P(\phi) \equiv \int \phi^2 dr$ is the soliton power (Kuznetsov et al., 1986). Orbital stability applies to filaments formed in saturable media with $f(s) = \alpha s - \beta s^2$, $f(s) = \alpha s/(1 + \beta s)$, or $f(s) = \alpha(1 - e^{-s})$, where α and β are positive constants. Relaxation of filaments to stable solitons promoted by the nonlinearity $f(s) = s/(1 + 2 \times 10^{-3}s)$ is shown in Figure 2.

On the whole, filamentation follows from linear stability analyses, which are valid as long as $\varepsilon(v + iw)$

Figure 2. Filamentation pattern numerically computed for a Gaussian beam with $P_{\text{in}} = 20P_C$ in a saturable medium.

remains smaller than ϕ , thus applying to early stages in the beam propagation. At later stages, filaments develop into a fully nonlinear regime, and they may interact. From the interplay between diffraction and nonlinearity, two filaments with radius ρ and separated by the distance $\Delta > 2\rho$ can fuse whenever Δ is below a critical value, Δ_c . This critical distance can be evaluated by the balance between the free and interaction contributions in the Hamiltonian of Equation (1) (Bergé et al., 1997). With no saturation, each filament whose

Figure 3. Filamentation and coalescence event in a two-spot pattern produced by a 50 fs pulse with 5 mJ energy propagating in air at the increasing distances (from left to right and from top to bottom): $z = 2.5, 4.5, 6.5$, and 8.5 m (Tzortzakis et al., 2001).

power is above critical creates its own attractor, at which it mostly freely collapses. This constraint is softened by including saturation, so that filaments with powers above critical are able to coalesce into an intense central lobe. As an example, the coalescence of two spots resulting from the propagation of modulationally unstable femtosecond pulses in air is shown in Figure 3 (Tzortzakis et al., 2001).

Modulational instability and multisoliton-like generation take place in various nonlinear media, such as biased photorefractive crystals or quadratically nonlinear optical materials favoring the coupling of fundamental and second harmonic fields (Fuerst et al., 1997). Filamentation moreover occurs in inertial fusion confinement (IFC) experiments as a harmful instability destroying the homogeneity in the beam energy distributed in the focal spot. For IFC, it has detrimental consequences to the hydrodynamics of the plasma created by a laser beam and contributes to the growth of parametric instabilities, which dissipate part of the laser energy. To limit its influence, optical smoothing techniques can be employed. For instance, random phase plates are used to generate a diffraction pattern composed of speckles, whose size λ_{sp} is smaller than the optimal wavelength λ_{mod} that maximizes the filamentation growth rate. This contributes to suppress laser filamentation (Labaune et al., 1992).

FITNESS LANDSCAPE

The notion of landscape is chosen in analogy to terrestrial landscapes, which are functions over a two-dimensional space, $f(x, y)$. Commonly, landscape is altitude h as a function of latitude θ and longitude φ : $h(\theta, \varphi)$. In the history of physics, the landscape concept was first applied to motion in the gravitational field resulting in the concept of a potential energy surface. The gravitational potential V depends on altitude, latitude, the mass of the particle m , and the gravitational

acceleration on the surface of the Earth as a function of latitude, $g(\theta): V(\theta, \varphi) = m g(\theta) h(\theta, \varphi)$. The metaphor of a landscape embedded in the gravitational field suggests an exploration of optimal downhill paths following the negative gradient of the potential, $-\text{grad } V(\mathbf{x}) = -(\partial V/\partial x_1, \partial V/\partial x_2, \dots, \partial V/\partial x_n)$, with infinitesimal step width and vanishing kinetic energy corresponding to infinitesimally slow motion.

The landscape metaphor is used today in many different disciplines where the optimization of a nonsimple cost function is the primary goal. Such a cost function may depend on any number of variables, for example, spatial coordinates and strengths of external fields, and then the space upon which a landscape is built will be high-dimensional. Landscapes describing complex systems exhibit a large number of local minima and maxima. Models of disordered systems, spin glasses in particular, were the first examples studied in detail. Spin glasses are traditionally studied by statistical mechanics and still represent the best-studied cases of statistics on complex landscapes (Binder, 1986; Dotsenko et al., 1990).

The notion of fitness landscape was introduced into evolutionary biology by Sewall Wright in 1932 as a metaphor for the visualization of Darwinian evolution as an optimization process (see Wright, 1967). The Darwinian mechanism operates on populations over the course of many generations. It is based on genetic variation of individuals through mutation and recombination and selection of the variants with largest reproductive success. Reproductive success of a genotype I is measured in terms of its fitness value f , which counts the number of (fertile) descendants in the next generation. The concept of a fitness landscape or mapping ϕ assigns a fitness value f_k to every genotype I_k : $\phi(I_k) = f_k$. Population genetics describes the evolution of a population by means of the time dependence in the distribution of genotypes: At time t the genotype I_k is assumed to be present with frequency $x_k(t)$ in a population of N individuals distributed over n types or variants. The frequencies fulfill $\sum_{k=1}^n x_k = 1$, and for asexual reproduction, we have $dx_k/dt = x_k(f_k - \bar{f})$ with $\bar{f} = \sum_{k=1}^n x_k f_k$ being the mean fitness of the population. The time derivative of the mean fitness,

$$\frac{d\bar{f}}{dt} = \bar{f}^2 - (\bar{f})^2 = \text{var}\{f\} \geq 0, \quad (1)$$

is equal to the variance of the fitness. The mean fitness of a population is a nondecreasing function of time and, hence, subjected to optimization. The frequencies of all variants with fitness values larger than average, $f_k > \bar{f}$, increase whereas those of genotypes that are less productive than average, $f_k < \bar{f}$ decrease until the genotype becomes extinct. This process continues until the mean fitness $\bar{f}$ has reached its maximum because all variants except the fittest have

Figure 1. Fitness landscapes illustrated by two consecutive mappings, one from genotype space into phenotype space and the other from phenotype space into the positive real numbers, $\mathbb{R}_+$, representing the fitness values. In agreement with the available data on biopolymer landscapes, we are dealing with the phenomenon of neutrality: There are many more genotypes than phenotypes, and different phenotypes may have fitness values that cannot be distinguished by selection.

disappeared. The optimization principle also holds for sexual reproduction with recombination, as long as variants at a single gene locus are considered, and is called Fisher's fundamental theorem in this context. More general models of population dynamics describe variation explicitly. When mutation is included and several genetic loci are considered, the optimization principle is no longer valid. However, it works in the mild form as an optimization heuristic in the sense that optimization is observed in almost all cases.

The dichotomy of biological evolution—genetic variation in the form of mutation and recombination changes genotypes, whereas selection operates on phenotypes—suggests a splitting of the conventional fitness landscapes into two successive mappings: Genotypes are mapped onto a space of phenotypes, and the phenotypes are evaluated by a second map to yield fitness values (Figure 1):

Biological evolution:

genotype $\Rightarrow$ phenotype $\Rightarrow$ fitness,

RNA evolution:

sequences $\Rightarrow$ structure $\Rightarrow$ replication rate.

Evolution experiments with RNA molecules in the test tube (Biebricher & Gardiner, 1997) are sufficiently simple to allow for a description of the fitness landscape in molecular terms. The RNA sequence forms a molecular structure that determines the replication rate parameters that are the molecular counterparts of fitness values.

In biological landscape metaphors, the genotypes are materialized as polynucleotide sequences, DNA or RNA. These are strings built from four classes of symbols, $\{\mathbf{A}, \mathbf{T}(\mathbf{U}), \mathbf{G}, \mathbf{C}\}$. In RNA $\mathbf{T}$ is replaced by $\mathbf{U}$. All sequences of given chain length are subsumed in a discrete sequence space, $\mathcal{I}$, with the Hamming distance between two sequences I_i and I_j , $d_{ij}^{(h)}$ serving as metric. The fitness landscape can be expressed by

$$\phi: \{\mathcal{I}; d_{ij}^{(h)}\} \Rightarrow \mathbb{R}_{(+)}, \quad (2)$$

where the plus sign implies a restriction to strictly positive fitness values. The structures are points in another discrete metric space $\mathcal{S}$ with some distance measure between structures $d_{ij}^{(s)}$. The fitness landscape is properly split into two mappings

$$\psi : \{\mathcal{I}; d_{ij}^{(h)}\} \implies \{\mathcal{S}; d_{ij}^{(s)}\}$$

and

$$f : \{\mathcal{S}; d_{ij}^{(s)}\} \implies \mathbb{R}_{(+)}. \quad (3)$$

Sequence-structure maps of RNA have been studied by means of computer models (Schuster, 2001, 2003) on the simplified level of RNA secondary structure. As sketched in Figure 1, the number of sequences is much larger than the number of secondary structures. Hence, many sequences may give rise to the same structure. In population biology this phenomenon is known as neutrality in sequence space, and it was discussed already in the 1980s by Kimura (1983) when the first biopolymer sequences became accessible. Neutrality was also found to be highly relevant for the efficiency of evolutionary processes because it allows for escape from local optima that would otherwise trap populations for long times (Fontana & Schuster, 1998).

The nature of landscapes can be analyzed by means of an expansion of the landscape in eigenfunctions of the Laplacian on the underlying discrete space (Reidys & Stadler, 2002). The expansion coefficients of this expansion allow for estimates of the hardness of optimization. Whenever we have only a single dominating expansion coefficient, the optimization problem is much simpler than in the case of equally important blending of two or more eigenfunctions. Biopolymer landscapes of free energies of conformations or other relevant properties turned out to be rather complex as several eigenfunctions of the Laplacian were found to be important.

FITZHUGH–NAGUMO EQUATION

Around 1960, Jin-ichi Nagumo (from the University of Tokyo) visited with Richard FitzHugh (at the U.S. National Institutes of Health), who was adapting the relaxation-oscillator models of Karl Bonhoeffer and Balthasar van der Pol to provide a more simple formulation of nerve membrane switching than the four-variable Hodgkin–Huxley system. From this visit emerged the FitzHugh–Nagumo (FN) system as a two-variable oscillator model (FitzHugh, 1961), which led to a simplified formulation of neural action potentials (Nagumo et al., 1962).

Neurons display relaxation oscillations par excellence. When the voltage across the cell membrane (in the trigger zone of the soma) exceeds a threshold, they fire an action potential and then gradually decay to the resting state. If the exciting input is constantly above the threshold, the neuron fires repeatedly. The frequency of such firing depends on the intensity of the input (total input coming from neighboring neurons). FitzHugh sought to reduce the Hodgkin–Huxley model of this dynamics to a two-variable model for which phase-plane analysis applies. His general observations were that the gating variables of the Hodgkin–Huxley model, n (potassium activation) and h (sodium inactivation), have slow kinetics relative to m (or sodium activation), and that for typical nerves $n+h \approx 0.8$. Furthermore, FitzHugh noticed that the voltage nullcline had the shape of a cubic function and the n -nullcline could be approximated by a straight line, both within the physiological range of the variables. This led to the following two-variable model that provides a phase space qualitative explanation of the formation and decay of the action potential.

$$\begin{aligned} \dot{v} &= +v(v - \theta)(1 - v) - y + I, \\ \dot{y} &= \varepsilon(v - \gamma y), \end{aligned} \quad (1)$$

where the dots indicate time derivatives.

Like all relaxation oscillators, this oscillator has a slow accrual phase and a fast release phase. Here v is the scaled voltage or membrane potential (namely, the output of the neuron), and y the single recovery variable accounting for the slow dynamics (sodium inactivation and potassium activation variables). The difference in time scales between sodium activation (m) and sodium inactivation and potassium activation (n and h) is represented by $\varepsilon \ll 1$. As ε increases, so does the frequency of oscillation. The constant γ

is a shunting parameter, $0 < \theta < 1$ is a thresholding parameter, and I is an externally applied current.

Such oscillators exhibit the characteristic dynamics of a real neuron. When fed by a constant amount of low current, the oscillator gradually increases its voltage (or membrane charge) until it reaches the threshold. Upon reaching threshold, the neuron fires and quickly releases the accumulated charge. If the current source is sufficient and is constantly applied, this results in stable limit-cycle oscillations.

The FN oscillator is applied in neuroscience to study the synchronization properties of neurons, which is particularly easy for relaxation oscillators such as the FN model. Following the Hebbian rule, neurons that fire closely in time strengthen their synaptic connections, and therefore synchronization in neural activity is important to the way the states of a brain evolve in time. Furthermore, information in neural tissues seems to be coded in the spatiotemporal firing of sets of neurons that fire synchronously, and tissues that are anatomically separated may operate together when they are synchronized.

An ensemble of coupled excitable oscillators of the FN type makes up an excitable medium, through which electrical signals can propagate. This is the case for a nerve and for other excitable media such as muscles. To model the spatiotemporal evolution of membrane potential and its generated current flows in such structure, one treats the axon or dendrite branch of the nerve as a membrane cylinder, with x denoting the distance along the cylinder. If ρ is the intracellular resistivity (in ohm-cm) and d the diameter, then the axial current is

$$I_i = -(\pi d^2/4\rho) \frac{\partial V}{\partial x}, \quad (2)$$

which follows directly from Ohm's law. Conservation of current then requires

$$C_m \frac{\partial V}{\partial t} = \frac{d}{4\rho} \frac{\partial^2 V}{\partial x^2} - I_{\text{ion}} + I(x, t), \quad (3)$$

where I_{ion} is the ionic current flowing through a unit area of the membrane surface and $I(x, t)$ and C are an external current and membrane capacitance per unit area.

Applying Equation (3) to the FN case, suggests that the electrical propagation in nerves can be represented as a reaction-diffusion system of the form

$$\begin{aligned} \frac{\partial^2 V}{\partial x^2} - \frac{\partial V}{\partial t} &= +F(V) - Y + I(x, t), \\ \frac{\partial Y}{\partial t} &= \varepsilon(V - \gamma Y). \end{aligned} \quad (4)$$

Here $F(V)$ is a function with cubic shape such as $F(V) = V(V - \alpha)(1 - V)$ or some similar function. [Such diffusion models can also be extended to more dimensions with $\partial^2 V / \partial x^2 + \partial^2 V / \partial y^2$ and $V(x, y; t)$.]

Under a traveling-wave analysis, let $I(x, t) = 0$ and $z = x + ct$ and define $dV/dz \equiv W$. Then Equations (4) become a system of ordinary differential equations

$$\begin{aligned} \frac{dV}{dz} &= W, \\ \frac{dW}{dz} &= F(V) - Y + cW, \\ \frac{dY}{dz} &= \frac{\varepsilon}{c}(V - \gamma Y), \end{aligned} \quad (5)$$

where one seeks traveling-waves solutions as trajectories $(V(z), W(z), Y(z))$ that approach the origin $(0, 0, 0)$ as $z \rightarrow \pm\infty$ (Scott, 2003).

With $\varepsilon = 0$, Y is constant. In this case, the only stable traveling wave solution is a level change from one of the outer zeros of $F(V) - Y$ to the other; in other words, a moving impulse-like solution does not exist. For $0 < \varepsilon \ll 1$, however, there is an impulse-like traveling-wave solution (or solitary wave). At arbitrarily small values of ε , this solitary wave continues to exist but with the front and back edges of the wave becoming far apart. These front and back edges interpolate between the slowly varying regions and are called boundary layers (as in hydrodynamics). As $\varepsilon \rightarrow 0$ on a scale where the impulse length is unity, the boundary layers reduce to step functions.

One of the main research areas related to these reaction-diffusion models in electrophysiology focuses on pattern formation and cardiac rhythm disturbances. FN equations have been used to investigate a variety of unusual front-bifurcation and pattern-formation processes. The precise conditions for wave front formation and subsequent wave propagation in an excitable medium are critical for understanding the genesis and possible control of re-entrant (spiral-wave) cardiac arrhythmias.

FLAME FRONT

Combustion waves can propagate over a wide range of burning velocities that differ by more than three orders of magnitude for the same mixture. At one end of the velocity spectrum, we have a laminar flame (deflagration) that propagates at a typical velocity of about half a meter per second for common fuel-air mixtures at normal conditions. At the other end, the combustion wave propagates as a detonation whose speed is of the order of a couple of thousand meters per second in the same mixture. In between these limits, we have an almost continuous range of turbulent burning velocities. Both laminar flames and detonation wave are intrinsically unstable and have the morphology of a transient cellular structure (Figure 1).

A laminar flame is essentially an isobaric diffusion-reaction wave. Its propagation speed is determined by the rate of diffusion transport of heat from the reaction zone to the cold unburned mixture and the characteristic time of heat release of the chemical reactions. A laminar flame speed (S_L) is proportional to the square root of the product of thermal diffusivity (D_{th}) and the reaction rate (w_r) (i.e., $S_L \sim \sqrt{D_{th} w_r}$). The reaction rate is given by $w_r \sim \exp(-E/RT_f)$ in which E is the activation energy and T_f is the flame temperature. Because the activation energy is very large in general, the reaction rate is extremely temperature sensitive. Thus, any fluctuation in the flame temperature will result in a large variation in the reaction rate leading to the development of instability of the flame front. Due to the large density and temperature changes across the flame, a strong thermal expansion of the burned gas results from the conservation of mass. The flame as a strong density interface as well as an expansion wave is subject to a number of dynamic instability mechanisms in the presence of an acceleration field. Furthermore, competition between heat and mass diffusion across the flame results in thermal diffusion instability. Rapid density changes across the flame also give rise to acoustic wave generation that can couple with increase in burning rate to induce acoustic driven instability. Thus, in practice, there is a wealth of instability mechanisms that render laminar flames unstable. Various instability mechanisms can be at work simultaneously and can influence each other. However, historically, each instability mechanism was isolated and studied individually and was, thus, named after the original researchers.

The flame as a density interface is unstable when subjected to an acceleration field (for example, gravity). If the flame propagates upward, the light burned gas (ρ_b) is at the bottom and the heavy unburned gas (ρ_u) is on the top. The lighter fluid will be driven upward (i.e., buoyancy) whereas the heavier fluid is driven

Figure 1. Cellular structures of laminar flame and detonation front. (a) Laminar outward propagating spherical flame (rich dimethyl ether-air at equivalence ratio of 1.2 and 10 atm). (b) Detonation: unstable cellular detonation front as recorder upon reflection from a soot-coated glass plate ($C_2H_2-O_2$ mixture at 10 mmHg).

downward by gravity (g). This motion will destabilize the interface, and hence, small perturbations on the flame surface will grow with time (t). If the perturbed flame surface (F) is defined as $A \exp(\sigma t + ikx)$, where k is the wave number and x the space coordinate, the disturbance growth rate σ can be determined from normal mode stability analysis as

$$\sigma = \sqrt{gk\gamma/(2 - \gamma)}, \quad \gamma = 1 - \rho_b/\rho_u. \quad (1)$$

Therefore, instability occurs at all wavelengths but growth is faster at shorter wavelengths. This phenomenon was first discovered by Lord Rayleigh (1883) and later by Geoffrey Ingram Taylor (1950), and thus, it is referred to as the Rayleigh–Taylor instability. This instability is common to all density gradient fields in the presence of an acceleration field normal to it.

Due to the density change across the flame, the flow velocity increases as the density ratio because the flame is approximately isobaric. The expansion across

the front will induce a divergent flow field ahead of a curved flame (Williams, 1985). This divergence slows down the local flow speed ahead of the curved flame front, and assuming the flame speed to be constant, this will result in a growth of the curvature of the flame. This instability was first discovered by G. Darrieus (1938) and Lev Landau (1944). The Darrieus–Landau instability was obtained by treating the flame as a surface of discontinuity moving at a constant speed. In the limit of small density change, stability analysis gives the growth rate as

$$\sigma = \gamma k S_L / 2. \quad (2)$$

Therefore, it was concluded that a flame front is unstable to perturbations at all wavelengths, with growth rate proportional to wave number (i.e., perturbations grow faster for small wavelengths). Unfortunately, this conclusion was contrary to later laboratory observations of small-scale stable flames.

The deficiency of this model was the result of neglecting the finite thicknesses of the flame front, which influences the flame speed when the flame is curved. To include the effect of flame thickness, George Markstein (1951) proposed a phenomenological model by adding a modification of flame speed due to curvature and showed that curvature decreases the flame speed and tends to stabilize the flame at short wavelengths inhibiting its growth. A more rigorous derivation of the dispersion equation including diffusion effect on the flame speed (in the limit of small density jump) was given later by Gregory Sivashinsky (1983) as

$$\sigma = \frac{\gamma k S_L}{2} - \left[\frac{\beta}{2} (Le - 1) + 1 \right] \times D_{th} k^2 - 4 \frac{D_{th}^3}{S_L^2} k^4 + \sqrt{g \gamma / (2 - \gamma)}, \quad (3)$$

where $D_{th} k^2$ in the second term of Equation (3) represents the thermal relaxation via transverse thermal diffusion that stabilizes the flame. Le is the Lewis number (i.e., the ratio of thermal diffusivity to mass diffusivity) and $(Le - 1)$ in the second term denotes the competition between heat loss via thermal diffusion and the enthalpy gain via mass diffusion. As a result, flame temperature will increase or decrease if Le is less or larger than unity. Equation (3) shows that if $Le - 1$ is less than $-2/\beta$ (β is the reduced activation energy), diffusion transport will destabilize the flame. This is the mechanism of the cellular instability. The third term in Equation (3) is the thermal relaxation to the modification of flame temperature caused by the heat and mass diffusion (Clavin, 1985). Therefore, for long wavelength disturbance, the hydrodynamic instability dominates (Figure 1a). At short wavelengths, diffusion relaxation stabilizes the flame. At moderate

wavelengths, the competition between heat and mass transfer induces cellular instability at small Le . At large Le , flame temperature is very sensitive to the mass diffusion of the deficient reactant. Coupling between the diffusion and temperature sensitive reaction yields pulsating and spinning waves. This traveling wave is often seen in lean propane-air flames.

By further considering the effect of flame curvature on flow field, Equation (3) can be normalized as an evolution equation of flame front

$$F_t + \frac{1}{2}(\nabla F)^2 + \nabla^2 F + 4\nabla^4 F = 0 \quad (4)$$

This is the so-called Kuramoto–Sivashinsky equation which was independently developed by Yoshiki Kuramoto (Kuramoto & Tsuzuki, 1976) for the study of phase turbulence in the Belousov–Zhabotinsky reaction and by Gregory Sivashinsky (1983) for thermal diffusive instabilities of flame fronts. This equation has also been used to model directional solidification and weak fluid turbulence. However, the assumption of small density jump used in Equations (3) and (4) is not rigorous in practical flames. A unified model considering large density jump and Le was obtained by Class Andreas et al. (2003).

Heat release by combustion results in an increase in the specific volume of the product gases and thus generates acoustic waves (Chu, 1956). The acoustic waves play two roles in affecting combustion: (1) inducing pressure–heat release coupling via pressure-dependent reactions, and (2) increasing flame surface area via the baroclinic torque (Meshkov instability). If the changes of pressure and chemical heat release are in phase, the acoustic instability occurs (Rayleigh, 1877; Markstein, 1953; Clavin, 2002). Lord Rayleigh first used this criterion (Rayleigh criterion) to explain the singing flame and Rijke’s tone (where heating the bottom of a tube causes it to produce sound). The acoustic instability causes the major problems of noise and vibration in combustors (Putnam & Dennis, 1953). On the other hand, volumetric heat loss reduces the flame speed and changes the resident time of the emitting gases. This coupling triggers the radiation induced instability for weak flames (Ju et al., 2000).

At the upper limit of propagation of combustion waves, the propagation mechanism is not due to diffusion. The flame instability mechanisms discussed above are too slow to be relevant in detonation wave instability. A detonation wave is a supersonic compression wave where mixture is ignited by the adiabatic compression of the leading shock. The classical structure of a detonation wave was formulated by Yakov Zeldovich, John von Neumann, and W. Döring (ZND) independently in the early 1940s and consists of a leading shock followed by the reaction zone after a short induction length (Zeldovich, 1940; von Neumann, 1942; Döring, 1943). Gas dynamic theory gives the detonation wave speed as proportional

to the square root of the chemical heat release and does not involve any non-equilibrium rate processes. Again due to the high-temperature sensitivity of the reaction rates, small temperature fluctuations due to variation of the leading shock speed will result in large variations in the induction length and reaction rates, hence the coupling between the energy release zone and the leading shock. The instability yields a transient three-dimensional cellular detonation front (Lee, 1984). The unstable cellular detonation front consists of an ensemble of interacting transverse shock waves with the leading shock front. The cell boundaries (Figure 1b) are formed by the intersections of the transverse shocks. Shock interactions (Mach reflections) also give rise to the formation of shear layers which lead to turbulence generation due to Kelvin–Helmholtz instability. Chemical reactions in cellular detonations occur in disjointed piecemeal zones embedded within the complex of interacting shocks and shear layers.

The instability of the laminar ZND detonation structure was demonstrated theoretically by standard normal mode stability analysis using the one-dimensional Euler equation (e.g., Erpenbeck, 1964; Lee & Stewart, 1990). In one dimension, unstable detonations are referred to as pulsating detonations that go from harmonic oscillations near the stability limit to highly nonlinear and eventually to chaotic oscillations with the increase of the activation energy. By examining the bifurcation diagram, it is interesting to find that the path to higher instability mode follows closely the Feigenbaum route (Feigenbaum, 1983) of a period-doubling cascade observed in many nonlinear systems. One-dimensional pulsating detonation as well as two- and three-dimensional cellular detonations have been reproduced qualitatively via numerical simulation using the reactive Euler equations (Bourlioux et al., 1991; Short & Stewart, 1999). However, the detailed description of the turbulent structure and chemical reactions requires resolutions far beyond current computing capabilities.

In between the two limits of laminar flames and detonations, there is a continuous range of flame speeds that depend on turbulence. The morphology of a turbulent flame is a time-dependent cellular or wrinkled surface. Turbulent flame is, in fact, an unstable flame, and the effect of turbulence is to increase the burning rate via faster transport and increase in burning surface area. In the limit of very intense turbulence where mixing and reaction rates are comparable, auto-ignition may result, and thus, the mechanism becomes similar to that of a detonation. It differs only in the manner in which auto-ignition is achieved by turbulent mixing of fresh mixture with hot products or by adiabatic heating of the leading shock. Thus, nature tends to maximize the burning rate of a mixture, and instability is a route to optimize the burning rate for given initial and boundary conditions.

FLIP-FLOP CIRCUIT

A bistable circuit is one that can exist indefinitely in either one of two stable states and that can be induced to make an abrupt transition from one stable state to the other by means of an external excitation. Bistable circuits are known by a variety of names, such as bistable multivibrator, Eccles–Jordan circuit (after the inventors), trigger circuit, binary, and flip-flop, the latter being the term that we adopt. Flip-flops are used for the performance of many digital operations such as counting and storing of binary information.

In general, digital (switching) circuits may be either combinational or sequential. In combinational circuits the Boolean relation that describes the output function is at any moment uniquely determined by the inputs. The output function is independent of all prior input or output conditions and the circuit is without memory. In contrast, the sequential circuit contains feedback and its outputs depend not only on the present inputs but, in general, also on the entire past history of inputs. The flip-flop is a basic sequential circuit that functions as a basic logic memory element. It has two distinct states of equilibrium and may, therefore, be used as a single binary-digit (bit) storage device. The two stable states are referred to by various names such as TRUE and FALSE, HIGH and LOW, or 1 and 0.

Sequential circuits can be presented using a graphical tool known as a state diagram. In a state diagram, nodes are used to represent the different states of a circuit, and connections between nodes are used to show transitions between states with different inputs that act as conditioning signals. Figure 1 represents a general bistable circuit. Let us denote the present state of the circuit as $Q(t)$ and the state that follows after a time interval Δt as $Q(t + \Delta t)$. Then the circuit stays in state 1 as long as condition 1 is applied, but moves to state 0 when condition 2 is applied. Similarly, it stays in state 0 as long as condition 3 is applied, and moves to state 1 when condition 4 occurs.

Four types of flip-flops are presently in use, RS (conditional Set and Reset), JK (unconditional set and reset), D (Delay), and T (Trigger), and they have different sets of conditions for transition between the two states. For example, the characteristic equation for

Figure 1. State diagram of a general bistable circuit.

Figure 2. Basic switching elements, (a) AND and (b) OR. An ideal switch consists of a pair of contacts that have zero internal (or switch closed) resistance and infinite leakage (or switch open) resistance. Transitions from one state to the other should be instantaneous. It should attain the open and closed states with equal probability. Although these characteristics have been approached most closely with every new technological generation, we deal in reality with approximations to them.

the RS flip-flop is given as

$$Q(t + \Delta t) = S + Q(t) \cdot \bar{R} \quad (1)$$

under the constraint

$$S \cdot R = 0. \quad (2)$$

Here + (OR), $\cdot$ (AND), and $\bar{}$ (NOT, also known as inversion and complement) are operations from switching algebra. Switching circuits which represent the AND, $A \cdot B$, and the OR, $A + B$, functions are presented in Figures 2a and b, respectively.

The mathematical theory of switching circuits, first postulated by Shannon (1938, 1949), is based on Boolean algebra. It is defined on a set U that consists of two values, 0 and 1, two basic binary operations, $\cdot$ (which is also called AND, product or conjunction), and $+$ (which is also called OR, sum or disjunction), and a set of basic postulates that were derived and proven by Edward Huntington in 1904, based on the work of George Boole in 1847.

Switching circuits have been designed from various technologies; for example, vacuum tubes were used in their early development. They have become dramatically faster and dramatically smaller in size with every new technology. The advent of integrated circuits (ICs), in which many discrete components (diodes, transistors, and resistors) are fabricated at the same time on one chip of silicon, has led to many different types of switching circuits in IC form. Recent research in nanoelectronics has introduced the concepts of resonant tunneling diodes, electronic quantum cellular automata, single electron transistors, and molecular electronic devices.

Figure 3. The RS flip-flop with NAND gates (top) and its truth-table (bottom). Its characteristic equation is $Q(t + \Delta t) = \bar{S} \cdot \bar{Q}(t) = \bar{S} \cdot \bar{Q}(t) \cdot \bar{R} = S + Q(t) \cdot \bar{R}$. Here we used de Morgan's laws: for any two subsets A and B of the U , we have $A \cdot \bar{B} = \overline{A + B}$ and $\overline{A + B} = \bar{A} \cdot \bar{B}$.

The basic switching circuits are called gates. Often NAND and NOR gates are used, as they are easier to implement. The RS flip-flop can be designed simply by interconnecting a pair of two-input NAND gates, with appropriate feedback, as shown in Figure 3. The truth-table in Figure 3 gives input values, R and S , that condition changes from a present state $Q(t)$ to a next state $Q(t + \Delta t)$. It is constructed by considering the physical action of the circuit shown in the same figure. For example, to stay in state 1, the equivalent to input condition 1 in Figure 1 is $R = 0$, and S need not be defined; its value is $\times$. The entries marked with $\times$ correspond to “not allowed” or “don’t care” inputs because, under these conditions, when both R and S are present simultaneously, the operation of the circuit becomes uncertain.

The Δt is a delay that occurs between the present state and the next state. This delay is essential in the operation of sequential circuits. With respect to the delay, two types of sequential circuits can be distinguished: synchronous and asynchronous. The synchronous sequential circuits trigger on receiving a certain clock pulse. The maximum frequency of the clock is defined by the operational time of the slowest element in the circuit. State transitions in a synchronous sequential circuit thus occur with a constant frequency. The delay in asynchronous sequential circuits changes from transition to transition, i.e. $\Delta t \neq \text{const}$.

The RS flip-flop, introduced above, is a bistable multivibrator. It stays in one of two states that can be changed only when an external input is applied. If there are no external inputs, but one state causes a transition to the other state and this repeats continuously, the multivibrator is said to be astable. It is not stable in

either state and alternates between them at a specific frequency. The astable multivibrator is, in fact, a free-running oscillator. The frequency is usually determined by a capacitor placed between the two gates and a resistor in parallel with each gate. Thus the delay, Δt , and consequently the frequency, are determined by the values of the capacitor and resistors.

In general, every oscillator contains a positive and negative feedback loop at the same time. For example, a unit with one excitatory and one inhibitory neuron that are mutually connected is a neuronal oscillator. The model proposed by Wilson and Cowan (See **Inhibition**), who introduced an inhibitory neuron and by this a positive along with the negative feedback loop, is today known as the Wilson–Cowan oscillator. As the exchange of energy and matter is continuous in every biological process that is based on existence of both positive and negative feedback loops, an oscillator can be seen as a basic biological unit.

Flip-flop circuits are today used as a general paradigm for bistability in a very wide range of non-linear systems, one of many examples being the phenomenon of stochastic resonance (Fauve & Heslot, 1983).

FLUCTUATION-DISSIPATION THEOREM

In the 19th century, there were two schools of thought on the existence of atoms, those that believed in them and those that did not. Remarkably, it was not until the early 20th century that the experiments of Jean Perrin—summarized in his 1913 book *Atoms* (Perrin, 1913)—established once and for all the existence of atoms. One of the laws Perrin experimentally verified was the fluctuation-dissipation relation, which inter-relates the physical notions of randomness (through fluctuations) and determinism (through dissipation) (Montroll & West, 1979).

No matter how carefully experiments are done, they never yield the same value of a physical

observable from one measurement to the next. The collection of values from such measurements is called an ensemble, and the number of times a measurement falls in an assigned interval divided by the total number of measurements in the ensemble yields a probability, which when all the intervals are taken together yields a probability distribution function. The best representation of this ensemble of measurements is the mode of the distribution (or ensemble average) as first noted by Carl Friedrich Gauss (1809). The deviations of a physical observable from its average value are called fluctuations, which are typically small and random. In physical systems, the source of these fluctuations is thermal agitation of the atoms. Thus, the thermodynamic properties of an equilibrium physical system are determined by the probability density, through the averages, and not by the instantaneous values of the positions and velocities of the atoms.

The changes in macroscopic physical systems over time comprise a combination of deterministic dynamics and microscopically induced macroscopic fluctuations. Albert Einstein, in 1905, was the first to fully appreciate the influence of these fluctuations on macroscopic transport phenomena in his investigations of the phenomenon of equilibrium diffusion (Furth, 1956). Einstein showed that the strength of the fluctuations, as measured by their mean-square level through the diffusion coefficient, D , is directly proportional to the temperature of the ambient fluid, $kT/2$, which is the average kinetic energy per degree of freedom of the ambient fluid particles. The constant of proportionality between the temperature and the diffusion coefficient is the dissipation time per unit mass, λ/m , thereby inter-relating the fluctuations and dissipation of the medium through the particle's motion

$$D = \frac{2\lambda kT}{m}. \quad (1)$$

Equation (1) was the first fluctuation-dissipation relation and demonstrates that macroscopic fluctuations and dissipation have the same microscopic origin.

Two decades before Einstein's analysis of diffusion, Walther Nernst (1884) investigated the combined process of mobility and diffusion to determine the size of the charge on an individual particle. He established that the mobility is proportional to the ratio of the diffusion coefficient to the temperature, and the charge of the particle is the proportionality constant. This ratio is usually called the Einstein equation even though Nernst discovered it. One can more generally define the mobility of a particle as the terminal velocity per unit force, through a generalized Nernst relation

$$D = kT \times \text{mobility} \quad (2)$$

for any sort of particle that is free to move but is subject to frictional drag. The linear transport coefficient

(here the mobility) was only partially understood until Harry Nyquist (in considering the fluctuations in the current flowing through an electrical resistance) showed that the circuit impedance can be used to compute the fluctuations arising from the thermal agitation of the electrons (Nyquist, 1928). Nyquist's form of the fluctuation-dissipation theorem gives the mean-square voltage fluctuations as proportional to the product of the temperature and resistance, with the proportionality constant being the bandwidth. Alternatively, the temperature can be written as the ratio of the spectral density of the random fluctuations of the electromotive force $S_e(\omega)$ to the real part of the impedance $Z(\omega)$:

$$S_e(\omega) = 2kT \operatorname{Re} Z(\omega) \quad (3)$$

at the frequency ω . When the Nyquist relation (3) was first derived, the applicability of the underlying reasoning to other linear transport processes involving thermal noise was not appreciated.

Let us consider the dynamical equation constructed by Paul Langevin concerning the forces acting on a particle in a fluid (Langevin, 1908). The equation of motion for a particle of mass m is

$$m \frac{du}{dt} + \frac{u}{\mu} = F + f, \quad (4)$$

where u is the particle velocity, μ is the mobility (the inverse of the dissipation), F is an external driving force, and f is a fluctuating force with zero mean produced by the thermal agitation of the ambient fluid particles. The Fourier transform of Equation (4) yields the impedance for the particle $Z(\omega) \equiv \tilde{F}(\omega)/\tilde{u}(\omega) = i m \omega + \mu^{-1}$. The average of the transformed equation yields the Nernst relation for a constant external force: $\langle \tilde{u}(0) \rangle = \mu F$. The diffusion coefficient is given by the integral over the velocity autocorrelation function, which using Parseval's theorem can be written in terms of the velocity spectral density, $S_u(\omega)$, as

$$D = 2S_u(0). \quad (5)$$

This expression for the diffusion coefficient is valid for any form of the velocity autocorrelation function and velocity spectral density, under the condition that the underlying process is stationary in time.

In general, one can conclude that the autocorrelation function of the random force in a physical system is proportional to the dissipation in that system, with the proportionality constant given by the temperature kT . This relation can be summarized as

$$\langle f(t)f(t') \rangle = 2D\delta(t - t'), \quad (6)$$

so that the diffusion coefficient determines the strength of the fluctuations. Further, there are time-dependent

generalizations of this form of the fluctuation–dissipation relation, where the δ function is replaced with a memory kernel, as well as extensions from the classical to the quantum domain, see, for example, Lindenberg & West (1990) for a review. However, each elaboration contains essentially the same information, namely, that microscopic dynamics are amplified to macroscopic fluctuations and dissipation. A complete understanding of the macroscopic phenomena of fluctuations and dissipation therefore requires an understanding of microscopic dynamics.

FLUID DYNAMICS

The field of fluid dynamics is devoted to the study of flows of matter in the liquid or gaseous state or in the form of multiple phases including suspensions of solid particles in liquids or gases. While it is in principle possible (and sometimes appropriate) to apply Newton's laws to individual molecules of a fluid and to describe the flow as an average over trajectories of the particles (See **Molecular dynamics**), it is usually far more efficient to consider liquids and gases as a continuum and to apply the equations for the dynamics of continuous media.

Conservation Laws of Continuous Media

The laws of the conservation of mass, momentum, and energy can be written in the form

$$\frac{d}{dt} \int_V \rho d^3V = \int_V \frac{\partial \rho}{\partial t} d^3V = - \oint_{\partial V} \rho n_j v_j d^2A, \quad (1a)$$

$$\begin{aligned} \frac{d}{dt} \int_V \rho v_i d^3V &= - \oint_{\partial V} \rho v_i n_j v_j d^2A, \\ &+ \int_V \rho F_i d^3V + \oint_{\partial V} S_{ij} n_j d^2A, \end{aligned} \quad (1b)$$

$$\begin{aligned} \frac{d}{dt} \int_V \rho(e + v_j v_j/2) d^3V \\ &= - \oint_{\partial V} v_j n_j \rho(e + v_i v_i/2) d^2A \\ &+ \int_V \rho F_i v_i d^3V + \int_V \rho q d^3V \\ &+ \oint_{\partial V} v_i S_{ij} n_j d^2A - \oint_{\partial V} h_j n_j d^2A, \end{aligned} \quad (1c)$$

where V denotes an arbitrary volume fixed in space and ∂V denotes its surface. ρ is the density of the continuous medium, v_i is the velocity vector, and ρF_i is the body force density acting on the medium. A typical example for F_i is the acceleration of gravity. e is the internal energy per unit mass, ρq is the heat source density, and h_i denotes the heat flux. Contributions like absorption and emission of radiation have not been included explicitly in the energy balance (1c). But in optically thick media they can be subsumed under q and h_i . The index notation has been used where the index i refers to the coordinates 1, 2, 3 of a Cartesian system of coordinates and where the summation over indices occurring twice in any term is implied. Relativistic effects have been neglected in writing Equations (1) that are thus valid only for velocities small compared with the velocity of light.

The fundamental quantity of the dynamics of a continuous medium is the stress tensor S_{ij} which describes the surface force $S_{ij} n_j$ exerted on a surface element with the normal unit vector n_i . More exactly, $S_{ij} n_j$ is the force per unit area exerted by the material pierced by n_i on the material pierced by $-n_i$. The concept of the surface force was advanced long before the atomistic nature of materials became generally accepted. Surface forces in the ideal sense do not exist in nature. But since the forces between molecules in materials act only over atomic distances, the concept of surface forces has turned out to be very useful. The limitation should be kept in mind, however, in the fluid dynamical treatment of the dynamics of galaxies, for instance.

For applications of the conservation laws (1) it is convenient to formulate them in differential form by taking the limit $V \rightarrow 0$ and using Gauss' theorem,

$$\left(\frac{\partial}{\partial t} + v_j \partial_j \right) \rho + \rho \partial_j v_j = 0, \quad (2a)$$

$$\rho \frac{\partial}{\partial t} v_i + \rho v_j \partial_j v_i = \rho F_i + \partial_j S_{ij}, \quad (2b)$$

$$\frac{\partial}{\partial t} \rho(e + \partial_j (\rho v_j e)) = S_{ij} \partial_j v_i + \rho q - \partial_j h_j. \quad (2c)$$

In deriving (2b) from (1b) and (2c) from (1c), we have used relationships (2a) and (2b), respectively. While Equations (2) apply to all continua, including solid materials, for applications to fluids the stress tensor is separated into two parts,

$$S_{ij} = -p\delta_{ij} + S'_{ij}, \quad (3)$$

where p is the thermodynamic pressure and S'_{ij} is the part of the stress tensor which depends on viscous friction and other dissipative effects. Then $S'_{ij}\partial_j v_i \equiv \rho\Phi$ is the irreversible conversion of work into heat. After using (2b), we may write (2c) in the form

$$\frac{De}{Dt} + p \frac{D\rho^{-1}}{Dt} = \Phi + q - \rho^{-1}\partial_j h_j, \quad (4)$$

where the material derivative

$$\frac{D}{Dt} \equiv \frac{\partial}{\partial t} + v_j \partial_j \quad (5)$$

has been introduced that describes the change in time with respect to the frame of reference moving with the fluid. This is also referred to as the Lagrangian description in contrast to the Eulerian description where the time derivative at a fixed point in space is taken.

In applications, the pressure p and the temperature T are usually the most readily known thermodynamic variables. We thus use the relationship $e = h - p/\rho$ for simple materials where h is the specific enthalpy and obtain

$$dh = c_p dT + \left. \frac{\partial h}{\partial p} \right|_T dp = c_p dT + \frac{1}{\rho}(1 - \alpha T) dp, \quad (6)$$

where some simple thermodynamic relationships have been used and $\alpha \equiv \rho(\partial\rho^{-1}/\partial T)_p$ is the coefficient of thermal expansion. As a final result, we thus obtain the energy equation in its most useful form

$$T \frac{Ds}{Dt} \equiv c_p \frac{DT}{Dt} - \frac{\alpha T}{\rho} \frac{Dp}{Dt} = \Phi + q - \frac{1}{\rho} \partial_j h_j. \quad (7)$$

Fourier's law, $h_i = -\lambda \partial_i T$, is commonly used for the heat flux, and for laboratory applications, it is a good approximation to neglect $\alpha T \rho^{-1} D\rho/Dt + \Phi$ in comparison with $c_p DT/Dt$. In this case, the familiar heat equation

$$\left(\frac{\partial}{\partial t} + v_j \partial_j \right) T = q + \kappa \partial_j \partial_j T \quad (8)$$

is obtained where $\lambda = \text{const.}$ has been assumed and where $\kappa = \lambda/\rho c_p$ is the thermal diffusivity.

Dynamics of Inviscid Fluids

The simplest equation of fluid dynamics is obtained when viscous, elastic, and other effects are neglected

and $S_{ij} = -p\delta_{ij}$ is assumed. The resulting Euler equation,

$$\left(\frac{\partial}{\partial t} + v_j \partial_j \right) v_i = -\rho^{-1} \partial_i p + F_i, \quad (9)$$

is most easily solved when the fluid is incompressible and $\rho = \text{const.}$ can be assumed. In that case

$$\partial_j v_j = 0 \quad (10)$$

holds and an equation of state connecting ρ and p is not needed.

A more general form of the equations is obtained in the barotropic case when the density is prescribed as a function of the pressure alone as, for instance, in the form of a polytropic relationship

$$p = p_0 \left(\frac{\rho}{\rho_0} \right)^\gamma. \quad (11)$$

This expression is valid, for example, for adiabatic changes of an ideal gas in which case γ equals the ratio of specific heats, $\gamma = c_p/c_v$. The equation for sound waves can be obtained when Equations (2a) and (9) are linearized around the static equilibrium state with $\rho = \rho_0$, $p = p_0$,

$$\frac{\partial^2}{\partial t^2} \rho = \gamma \frac{p_0}{\rho_0} \partial_j \partial_j \rho, \quad (12)$$

where $\gamma p_0/\rho_0 = c_s^2$ is the square of the speed of sound. For general fluids, the relationship $c_s^2 = \partial p/\partial \rho$ holds. The ratio of a characteristic velocity divided by the sound speed is called the Mach number Ma . The domains of fluid flow with $Ma > 1$ are usually separated from regions with $Ma < 1$ by shock fronts in which energy is dissipated and frictional processes must be taken into account.

A fundamental consequence of Equation (9) is Kelvin's theorem,

$$\frac{D}{Dt} \oint_C \mathbf{v} \cdot d\mathbf{l} = 0, \quad (13)$$

where the integral is called the circulation and must be taken over a closed curve C moving with the fluid. Theorem (13) holds for barotropic fluids when the force field F_i is conservative; that is, it can be written as the gradient of a single-valued scalar function. The property that the circulation is an invariant of fluid motion represents an elegant formulation of Helmholtz's vortex theorem, which states that the strength of a vortex tube moving with the fluid remains unchanged,

$$\frac{D}{Dt} \int_S \nabla \times \mathbf{v} \cdot d^2 \mathbf{A} = 0, \quad (14)$$

where the surface S is bounded by a closed material curve, C . $\nabla \times \mathbf{v}$ is called the vorticity field of the velocity field $\mathbf{v}$. The manifold of vorticity vectors

intersecting the curve C generates as tangential vectors the surface of the vortex tube. Kelvin's theorem and Helmholtz's theorem are connected, of course, by Stokes' theorem.

An important consequence of theorem (13) or (14) is that motions starting in a fluid from rest have vanishing vorticity if the force field is conservative and viscous effects can be neglected. An incompressible fluid with vanishing vorticity obeys the equation

$$\mathbf{v} = \nabla \phi \quad \text{with} \quad \nabla^2 \phi = 0. \quad (15)$$

Such flows are called potential flows.

Dynamics of Viscous Fluids

In the general case, the stress tensor S'_{ij} may be a rather complex function of the properties of the fluid and its motions. The various problems arising in this connection are the subject of the field of rheology. Fortunately, the most important fluids such as air and water and many others can be described as Newtonian fluids for which a linear homogeneous relationship holds between S'_{ij} and the velocity gradient tensor $\partial_i v_j$,

$$S'_{ij} = \mu(\partial_i v_j + \partial_j v_i - \frac{2}{3}\delta_{ij}\partial_k v_k) + \tilde{\mu}\delta_{ij}\partial_k v_k, \quad (16)$$

where μ is the dynamic viscosity and $\tilde{\mu}$ is the bulk viscosity. It is difficult to measure the latter property. Because $\tilde{\mu} = 0$ can be shown to hold for mono-atomic gases, this relationship is often generally applied in which case the Navier-Stokes equations are obtained,

$$\rho \left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) \mathbf{v}_i = -\partial_i p + \rho F_i + \partial_j \left(\mu(\partial_i v_j + \partial_j v_i - \frac{2}{3}\delta_{ij}\partial_k v_k) \right). \quad (17)$$

For a given force field F_i , this equation together with the equation of continuity (2a) and a barotropic equation of state, $\rho = \rho(p)$, provides a complete set for the determination of the variables v_i , ρ , p (See **Navier-Stokes equations**).

An even simpler set of equations can be obtained for incompressible fluids with $\rho = \text{const.}$, $\mu = \text{const.}$,

$$\left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) \mathbf{v}_i = -\partial_i \frac{p}{\rho} + F_i + \nu \partial_j \partial_j v_i, \quad (18a)$$

$$\partial_j v_j = 0, \quad (18b)$$

where the kinematic viscosity $\nu = \mu/\rho$ has been introduced. Using U as typical velocity and d as a typical length scale, we find for the ratio of the last terms on the left- and right-hand sides of Equation (18a)

$$\frac{Ud}{\nu} = \text{Re} \quad (19)$$

which is called the Reynolds number. In the low Reynolds number limit, the Stokes equation is obtained

in which the term $v_j \partial_j v_i$ in Equation (18a) is dropped. In the high Reynolds number limit, the Euler equation does not become applicable, in general, because of the existence of a turbulent cascade where energy is transferred to smaller and smaller scales such that the term $v_j \partial_j v_i$ cannot be neglected in the limit $\nu \rightarrow 0$ (See **Turbulence**).

Buoyancy-driven Flows

Among the force fields that are not conservative and therefore tend to generate motions with vorticity, buoyancy forces are the most common ones. Especially in atmospheric, oceanic, and astrophysical applications, buoyancy-driven flows are of fundamental importance. In order to keep as much as possible of the convenient properties of the Navier-Stokes equations for incompressible fluids, the Boussinesq approximation is usually introduced in which the temperature dependence of the density, say $\rho = \rho_0(1 - \gamma(T - T_0))$, is taken into account in the gravity force term only, while ρ is replaced by ρ_0 elsewhere in the equations. Together with the heat equation, the following set of equations is obtained:

$$\left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) \mathbf{v} = -\nabla \pi - \gamma(T - T_0)\mathbf{g} + \nu \nabla^2 \mathbf{v}, \quad (20a)$$

$$\nabla \cdot \mathbf{v} = 0, \quad (20b)$$

$$\left(\frac{\partial}{\partial t} + \mathbf{v} \cdot \nabla \right) T = \kappa \nabla^2 T, \quad (20c)$$

where $\mathbf{g}$ is the gravity vector and where $\nabla \pi$ includes all terms that can be written as a gradient. Because the pressure dependence of the density is neglected in the Boussinesq approximation, the contribution Φ must also be neglected (Busse, 1989).

A simple solution described by these equations is the flow between two parallel plates with separation d that are kept at different temperatures and that are inclined at an angle χ with respect to the horizontal plane (see Figure 1).

$$\mathbf{v} = z(z^2 - d^2/4)\gamma g \sin \chi (T_2 - T_1)\hat{\mathbf{i}}, \quad (21a)$$

$$T = T_0 + (T_2 - T_1)z/d. \quad (21b)$$

A Cartesian system of coordinates has been assumed with the z -coordinate normal to the plates and the origin in the middle between the plates. $\hat{\mathbf{i}}$ is the unit vector in the direction of inclination parallel to the x -axis as shown in Figure 1. T_1 and T_2 are the fixed temperatures at the boundaries $z = -0.5$ and $+0.5$, respectively, and $T_0 = (T_2 + T_1)/2$. Since in laboratory realizations of this configuration the space between the plates will be enclosed by side walls, the condition that the total mass transport between the plates vanishes has been imposed. Of special interest is the case $\gamma(T_2 - T_1) < 0$

Figure 1. Inclined fluid layer heated from above.

when the density increases opposite to the direction of gravity such that an unstable stratification results. In a horizontal layer where solution (21a) vanishes, the instability occurs in the form of Rayleigh–Bénard convection. The dimensionless control parameter for this case, $Ra \equiv \gamma g(T_2 - T_1)d^3/\kappa\nu$, is called the Rayleigh number. Convection rolls set in when Ra exceeds a critical value Ra_c depending on the boundary conditions. Besides buoyancy driven rolls aligned with the x -axis for $\chi \neq 0$ hydrodynamic, instabilities may set in in the form of transverse vortices. Since these forms of secondary states of motion are themselves subject to secondary instabilities, sequences of bifurcations are observed leading to increasingly complex patterns of fluid flow as indicated in Figure 2 for a few examples. The variety of patterns that can be realized continue to be a subject of intense experimental and theoretical research (See **Taylor–Couette flow**).

A role similar to that of buoyancy is played by the temperature dependence of surface tension that may give rise to instabilities much like Rayleigh–Bénard convection. Instead of the parameter Ra , the Marangoni number $M = \xi(T_2 - T_1)d/\kappa\eta$ is used as a control parameter, in this case where $\xi = \partial\sigma/\partial T$ denotes the derivative with respect to temperature of the surface tension σ .

Dynamics of Rotating Fluids

The Navier–Stokes equations (17) are invariant with respect to a Galileo transformation; that is, they retain their form in the transition from one inertial frame of reference to another one. When the transformation is made from an inertial to a frame of reference rotating with the constant angular velocity Ω , it must be taken into account that the transformation of a vector field $\mathbf{a}$ is different from that of a scalar field ϕ ,

$$\frac{\partial}{\partial t'}\mathbf{a} = \left(\frac{\partial}{\partial t} + \Omega \times \mathbf{r} \cdot \nabla - \Omega \times \right) \mathbf{a}, \quad (22a)$$

$$\frac{\partial}{\partial t'}\phi = \left(\frac{\partial}{\partial t} + \Omega \times \mathbf{r} \cdot \nabla \right) \phi; \quad (22b)$$

that is, a constant vector field in an inertial frame becomes time dependent as seen from the rotating frame. Using $\mathbf{v}' = \mathbf{v} - \Omega \times \mathbf{r}$ where $\mathbf{r}$ is the position vector, we find as Navier–Stokes equation in the rotating frame

$$\begin{aligned} \left(\frac{\partial}{\partial t'} + \mathbf{v}' \cdot \nabla \right) \mathbf{v}' + 2\Omega \times \mathbf{v}' \\ = -\nabla \frac{P}{\rho} - \nabla \Psi + (\Omega \times \mathbf{r}) \times \Omega + \nu \nabla^2 \mathbf{v}' \end{aligned} \quad (23a)$$

$$\nabla \cdot \mathbf{v}' = 0. \quad (23b)$$

We have restricted our attention to the incompressible case with $\rho = \text{const.}$ and have assumed that the force field $\mathbf{F}$ is conservative, that is, $\mathbf{F} = -\nabla \Psi$. Because the centrifugal force is also conservative it can be combined with $\mathbf{F}$; that is, $\Psi' = \Psi - |\Omega \times \mathbf{r}|^2/2$ can be used as the potential. The other new term in Equations (23) is the Coriolis force, $-2\Omega \times \mathbf{v}'$, which is responsible for the fact that the dynamics of rotating systems is quite different from that of nonrotating systems. Since the Coriolis force is typically the largest term on the left-hand side of Equation (23a) and since viscous friction is usually negligible in the interior of the fluid, the approximate relationship

$$2\Omega \times \mathbf{v} = -\nabla \pi \quad (24)$$

is obtained which is called the geostrophic balance because of its importance in meteorology and oceanography. Here, $\rho\pi$ is the dynamic pressure, $\pi = p/\rho + \Psi'$, and for simplicity, the prime of $\mathbf{v}$ has been dropped. When the curl of balance (24) is taken and Equation (23b) is used, the famous Proudman–Taylor theorem is obtained,

$$2\Omega \cdot \nabla \mathbf{v} = 0. \quad (25)$$

This theorem states that in a rapidly rotating system, a steady velocity field of a nearly inviscid fluid must be independent of the coordinate in the direction of the axis of rotation. As a consequence, $\mathbf{v}$ will depend only on the x -, y -coordinates of a cartesian system with the z -coordinate pointing in the direction of Ω . Since $\mathbf{v}$ must also satisfy $\nabla \cdot \mathbf{v} = 0$, a single scalar function, the stream function ψ , is sufficient to describe $\mathbf{v}$. Assuming boundaries perpendicular to Ω , we find

$$\mathbf{v} = \nabla \psi \times \Omega / \Omega \quad \text{with} \quad \psi = -\pi(x, y)/2\Omega$$

and

$$\Omega = |\Omega|. \quad (26)$$

The form of the velocity field indicates that the flow parallels the isobars in contrast to the situation in a nonrotating system where the flow is usually directed perpendicular to the pressure gradient. The

Figure 2. Examples of bifurcation sequences.

geostrophic wind (26) flows cyclonically (i.e., in the sense of rotation) around low-pressure regions and anticyclonically around high-pressure regions, as can be seen on weather maps.

The fact that the function $\pi(x, y)$ has remained undetermined so far is known as the geostrophic degeneracy. Terms of higher order in the equations of motion are needed to remove this degeneracy and to introduce time dependences on scales much longer than the rotation period $2\pi/\Omega$ of the system. A three-dimensional nature of the velocity field enforced, for instance, by boundary conditions can thus be introduced as a perturbation of the geostrophic solution. Rossby waves are a typical example for the quasigeostrophic dynamical response of rotating fluid systems.

The friction term in Equation (23a) is characterized by the highest spatial derivatives and thus can become large wherever strong variations of the velocity field occur, as, for example, near solid boundaries where the tangential velocity component must vanish. Thin Ekman boundary layers are formed here with the typical thickness $\sqrt{\nu/\Omega}$. But internal shear layers in the interior of the fluid can also be realized. The Ekman number defined by

$$E = \nu/\Omega d^2, \quad (27)$$

where d is a typical length scale of the system in the

direction of the axis of rotation, is often used as a dimensionless parameter in the dynamics of rotating fluids.

FOKKER–PLANCK EQUATION

The Fokker–Planck equation (FPE) plays a role in stochastic systems analogous to that of the Liouville equation in deterministic mechanical systems. Namely, the FPE describes in a statistical sense how a *collection* of initial data evolves in time. To be precise, let the phase space describing the system be parameterized by the state vector $\mathbf{y}$, and let $\mathbf{Y}(t)$ denote the value of the state vector assumed by the system at time t . Suppose the dynamics of the system is governed by a stochastic differential equation (SDE) of the form

$$d\mathbf{Y}(t) = \mathbf{U}(\mathbf{Y}(t), t) dt + \sigma(\mathbf{Y}(t), t) \cdot d\mathbf{W}(t). \quad (1)$$

The deterministic component of the dynamics is described by the drift vector $\mathbf{U}(\mathbf{y}, t)$, while the random part is driven by a vector of independent Brownian motions $\mathbf{W}(t)$ that are coupled to the system through the matrix $\sigma(\mathbf{y}, t)$.

Alternatively, we can define the system dynamics as a “diffusion process” in the relevant phase space such that

$$\left\{ \begin{array}{l} \lim_{\tau \downarrow 0} \tau^{-1} (\mathbf{Y}(t + \tau) - \mathbf{Y}(t)) = \mathbf{U}(\mathbf{Y}(t), t), \\ \lim_{\tau \downarrow 0} \tau^{-1} \langle (\mathbf{Y}(t + \tau) - \mathbf{Y}(t)) \\ \quad \otimes (\mathbf{Y}(t + \tau) - \mathbf{Y}(t)) \rangle = 2\mathbf{D}(\mathbf{Y}(t), t), \\ \lim_{\tau \downarrow 0} \tau^{-1} \langle |\mathbf{Y}(t + \tau) - \mathbf{Y}(t)|^\gamma \rangle = 0 \text{ for } \gamma > 2, \end{array} \right. \quad (2)$$

where $\langle \cdot \rangle$ denotes an average over the random component of the dynamics. The SDE and diffusion process descriptions are equivalent, with $2\mathbf{D} = \sigma\sigma^\dagger$.

One useful way to describe the evolution of stochastic systems over a finite (rather than infinitesimal) time interval is through the probability transition density $p(t, \mathbf{y}|t', \mathbf{y}')$, which describes the likelihood that if the state variable assumes the value $\mathbf{y}'$ at time t' , then it will assume a value near $\mathbf{y}$ at the later time t . More precisely, p is defined in terms of conditional

probability as

$$\text{Prob}(\mathbf{Y}(t) \in B | \mathbf{Y}(t') = \mathbf{y}') = \int_B p(t, \mathbf{y}|t', \mathbf{y}') d\mathbf{y} \quad (3)$$

for all nice (Borel) sets B in the phase space. The FPE, also known as the Kolmogorov forward equation, is a partial differential equation that describes how the probability transition density evolves when the system can be described as an SDE (1) or diffusion process (2):

$$\left\{ \begin{array}{l} \frac{\partial p(t, \mathbf{y}|t', \mathbf{y}')}{\partial t} \\ = \frac{\partial}{\partial \mathbf{y}} \left(-\mathbf{U}(\mathbf{y}, t) p + \frac{\partial}{\partial \mathbf{y}} (\mathbf{D}(\mathbf{y}, t) p) \right), \\ p(t = t', \mathbf{y}|t', \mathbf{y}') = \delta(\mathbf{y} - \mathbf{y}'). \end{array} \right. \quad (4)$$

This equation is to be solved for $t > t'$ with fixed data for the source variables $(t', \mathbf{y}')$ and appropriate boundary conditions in $\mathbf{y}$ (Risken, 1989, Chapter 4).

The probability transition density can be used to describe the probability density for the state vector at any moment of time:

$$\text{Prob}(\mathbf{Y}(t) \in B) = \int_B \phi(t, \mathbf{y}) d\mathbf{y} \quad (5)$$

by simply integrating against the prescribed probability distribution of the states at the initial time t' :

$$\phi(t, \mathbf{y}) = \int p(t, \mathbf{y}|t', \mathbf{y}') \phi(t', \mathbf{y}') d\mathbf{y}'. \quad (6)$$

Alternatively, $\phi(t, \mathbf{y})$ can be shown to satisfy the FPE (4) but with initial data $\phi(t', \mathbf{y}')$ prescribed more generally as a nonnegative function with integral one rather than as a delta function.

The FPE was first applied to describe Brownian motion. In the most idealized case, where inertia is completely neglected, Einstein showed that the statistics of the position $\mathbf{x} = \mathbf{X}(t)$ of a Brownian particle obeys an FPE that coincides with the ordinary diffusion equation:

$$\frac{\partial \phi(t, \mathbf{x}|t', \mathbf{x}')}{\partial t} = \kappa \Delta_{\mathbf{x}} \phi, \quad (7)$$

where $\Delta_{\mathbf{x}}$ is the Laplace operator and the diffusion coefficient $\mathbf{D} = \kappa \mathbf{I}$ is a constant scalar multiple of the identity matrix. The stochastic differential description of this model is simply

$$d\mathbf{X}(t) = (2\kappa)^{1/2} d\mathbf{W}(t). \quad (8)$$

The effects of inertia and external forces can be incorporated by passing to a phase space description including both the position $\mathbf{x} = \mathbf{X}(t)$ and the velocity $\mathbf{v} = \mathbf{V}(t)$ of the Brownian particle. The equations of

motion can then be written in terms of Newton's law with a random forcing component proportional to $d\mathbf{W}$:

$$\begin{cases} d\mathbf{X}(t) = \mathbf{V}(t) dt, \\ m d\mathbf{V}(t) = -m\xi \mathbf{V}(t) dt + \mathbf{f}(\mathbf{X}(t), t) dt \\ \quad + (2k_B T m \xi)^{1/2} d\mathbf{W}(t), \end{cases} \quad (9)$$

where ξ is a friction coefficient, k_B is Boltzmann's constant, T is the absolute temperature, and $\mathbf{f}(\mathbf{x}, t)$ represents the deterministic part of the external applied force. The equivalent Fokker-Planck description for the phase space probability transition density in this system reads

$$\begin{aligned} \frac{\partial p(t, \mathbf{x}, \mathbf{v} | t', \mathbf{x}', \mathbf{v}')}{\partial t} \\ = \mathbf{grad}_v \cdot \left[\left(\xi \mathbf{v} - \frac{\mathbf{f}(\mathbf{x}, t)}{m} + \frac{k_B T \xi}{m} \mathbf{grad}_v \right) p \right] \\ - \mathbf{grad}_x \cdot (\mathbf{v} p) \end{aligned} \quad (10)$$

Observe how this equation generalizes the Liouville equation for deterministic mechanics to include Brownian motion. The simplified diffusion equation (7) can be obtained through an asymptotic limit of the full FPE (10) with $\kappa = k_B T / (m \xi)$, when $\mathbf{f}(\mathbf{x}, t) = 0$ and $(k_B T / (m \xi^2 \ell^2))^{1/2} \ll 1$ with ℓ a characteristic length of the system (Bocquet, 1997; Risken, 1989). A similar reduction to a partial differential equation in coordinate space, called the Smoluchowski equation, is also possible for collections of interacting particles where the friction tensor depends on the particle configuration (Titulaer, 1980). From the FPE for Brownian motion, one can compute various statistical properties such as its mean-square displacement, the spectrum of its fluctuations, the rate of relaxation of initial velocity to thermal equilibrium values, and the probability distribution for the time at which the particle first achieves a certain location or surmounts a potential barrier (Wax, 1954).

The FPE has found useful application in computing similar statistical properties in numerous other systems, such as lasers, polymers, particle suspensions, quantum electronic systems, molecular motors, and finance. In some instances, the system is not at first formulated in one of the senses (1) or (2) which immediately imply an FPE. Rather, the systems are more naturally represented in terms of a master equation with a complete description of the rates at which the system (randomly) jumps from one state to another. The FPE is an appropriate approximation to this system when certain asymptotic conditions, such as small jumps, a large system size, or a separation of time scales between resolved and unresolved variables, are met (Grabert, 1982; Risken, 1989; van Kampen, 1981).

A variety of techniques for practical analysis of FPEs can be found in Risken (1989). The main alternative to analyzing stochastic systems through the

FPE is through the stochastic differential (or Langevin) formulation (1). The FPE has the merit of being a deterministic partial differential equation that can be solved once through either analytical or numerical methods. The stochastic differential description (1) by contrast consists of ordinary differential equations for which individual realizations (samples) are faster to simulate through Monte Carlo methods (Kloeden & Platen, 1992). But obtaining a statistical description of the general behavior of the system requires the generation of a large number of realizations.

Certain statistical quantities described above can be easily calculated using either the solution of the FPE or by operating directly on the FPE itself. On the other hand, the stochastic differential system (1) must be used if one wishes to characterize particular realizations of the stochastic system. Moreover, the stochastic differential description can be readily generalized to cases in which the random driving has temporal correlations (Kubo et al., 1991; Moss & McClintock, 1989). The FPE formulation can be modified to a "fractional" formalism for certain self-similar temporal correlation structures (Metzler & Klafter, 2000), but further generalizations are much more complicated and usually require some sort of approximation (Moss & McClintock, 1989).

FORECASTING

The success of Newtonian classical mechanics led in the 18th and 19th centuries to a strong belief in determinism; that is, the notion that the past determines the present and the future. As a consequence, a superior intellect ("Laplace's Daemon") would be able to forecast the future given enough information about the present and the past. However, the discovery of chaos in a large class of deterministic nonlinear dynamical systems sets a limit as to what Laplace's Daemon can forecast.

One of the characteristics of deterministic chaos is that the future state of a dynamical system depends sensitively on the initial conditions—infinitesimal perturbations will grow exponentially. This effect is also known more poetically as the "butterfly effect" (from a lecture by Edward Lorenz in 1972: "Does the flap of a butterfly's wings in Brazil set off a tornado in Texas?"). Since there will always be some uncertainty—however small—about the observed state of any physical system, a consequence of extreme sensitivity on the initial conditions is that the future state of such a system can only be forecast to lie within a given error tolerance a limited time ahead. As even Laplace's Daemon would not be able to determine the exact present state of the system, she would not be able to forecast the state of the future, but as she would know the uncertainty about the present, she would be able to work out all possible future states.

Uncertainty in the initial conditions is appropriately expressed in terms of a multivariate probability density function (pdf). A forecast is then given by the time evolution of the initial pdf, subject to the underlying dynamical system. Typically, the initial pdf is sharp, centered around the best estimate of the observed state of the physical system, but with time the pdf is smeared out in a complicated fashion until, eventually, all information about the initial condition is lost. For the short-range evolution, when the pdf remains "sufficiently" sharp, a forecast can be given in deterministic terms. For the intermediate-range evolution, when the pdf still has sufficient structure, a forecast can (and should) be given in probabilistic terms. Beyond that, a forecast will be no better than a guess based on the observed long-term behavior of the system.

When the governing dynamical equations are known, the time evolution of the pdf can be expressed in terms of the Liouville equation, which is a special case of the stochastic differential Fokker–Planck equation. In theory, the Liouville equation could be applied to weather forecasting where dynamical models have been developed of the atmospheric circulation, but in practice, numerical problems and computational limits need to be overcome. An alternative approach is to make a Monte Carlo-type estimation of the time evolution of the pdf, that is, numerical integration of an ensemble of a large number of initial conditions that are generated by random sampling of the initial pdf. Application to weather forecasting of this Monte–Carlo approach is, however, also problematic, primarily due to the very high dimension ($\sim 10^7$) of the phase space of atmospheric circulation models that requires a very large number of Monte Carlo integrations to be performed (beyond the capacity of present-day supercomputers) in order to sufficiently reduce sampling uncertainty.

The practical approach that is applied to today's weather forecasting is to generate a relatively small ensemble (comprising typically 50–100 members) of initial perturbations to the observed initial state of the atmosphere. The perturbations are calculated in a way that ensures that the corresponding trajectories of the dynamical model equations initially diverge rapidly from the observed initial state. Thus, the time evolution of the individual ensemble members is not representative of the time evolution of the "true" pdf, but the ensemble is useful for the weather forecaster who is often most interested in the most likely development of the weather and possible major deviations from this development.

Forecasting becomes increasingly problematic when we also take into account that the forecast model is not perfect; that is, there are errors in the model (perhaps due to incorrect assumptions or poor spatial resolution), the effect of which is that the model does not behave like the real world. In the area of weather forecasting, model errors cause severe problems for long-range forecasts. A long-range weather forecast, or seasonal forecast, valid out to typically six months ahead, aims at predicting slowly varying surface conditions, such as sea surface temperature, sea ice cover, and soil moisture, and the effect they have on the preferred state of the atmospheric circulation in certain regions. A prominent example is prediction of El Niño conditions (increased sea surface temperature in the central and eastern tropical Pacific), which have an influence on worldwide weather.

The effect of model errors is in practice taken into account by basing seasonal weather forecasts on ensembles made up of integrations of more than one model. In this way, a pseudo-stochastic element is introduced into the forecast through the different

formulations of the models, particularly for processes that take place on spatial scales that are smaller than the resolution of the model grid.

Forecasting is also of interest in areas in which models are not readily expressed in terms of known physical laws, most notably, in economics. When a physical model is not available, forecasting has to be based on more empirical methods. For example, a statistical forecast model would be based on the forecaster's notion of cause and effect, while an empirically constructed dynamical model could be derived from analysis of the combined behavior of many observed variables.

Due to the nondeterministic nature of economic evolution, economic forecasts will often be associated with substantial uncertainty. However, it is worth noting that a forecast need not be very accurate to be useful. If, in the long run, an economic forecast is just slightly better than a guess, then money can be made from the forecast.

In practical forecasting, no matter in what field, there is almost always an element of human expert judgment involved, and overall the expert judgment probably remains the most widespread forecasting method.

FOREST FIRES

The modeling of forest fires (FF) is based upon the concept of interacting particle systems (Liggett, 1985) for the description of complex systems. Within this framework, attention is on the interactions among particles (i.e., the trees), disregarding any attempt to understand the behavior of each particular tree. Using local interaction rules among neighboring trees, interesting collective behavior can be observed on a global scale.

FF models are defined so that trees may grow on the nodes of a surface network with periodic boundary

conditions (Bak et al., 1990; Drossel & Schwabl, 1992, 1993; Christensen et al., 1993; Grassberger, 1993; Albano, 1995). Each node can assume three different states: (s1) occupied by a growing tree, (s2) occupied by a burning tree, and (s3) empty. The last corresponds to the absence of a tree that occurs after the completion of the tree burning process. Local interaction rules govern the dynamics of the system, which is updated as a cellular automation. For a given configuration, the time evolution is obtained by applying the following rules: (r1) a tree grows on an empty node with probability P ; (r2) a burning tree evolves into an empty node; and (r3) a tree catches fire from a neighbor burning tree with probability $1 - G$. Thus, P is the growing probability of trees and G is the immunity of each tree to catch fire (Drossel & Schwabl, 1993).

Qualitatively, one expects that if the immunity is nonzero, the fire fronts present for $G = 0$ will become more and more fuzzy when G is increased. Of course, the fire cannot propagate for $G = 1$. For large values of P ($P \rightarrow 1$) and if the immunity is low ($G \rightarrow 0$), one observes coexistence of fire, trees, and empty nodes. Within this active state, fire fronts exhibit a rich variety of spatiotemporal patterns, including the development of spirals, and the collision between fronts. However, by keeping P constant and increasing G , the fire will eventually cease and the system will become trapped in an inactive state where the network is completely occupied by trees (see Figure 1). Since the spontaneous ignition of trees is not considered, the system will remain in the inactive state forever. So, for some critical values of the parameters $P \equiv P_c$ and $G \equiv G_c$, this simple kind of FF model exhibits irreversible phase transitions (Marro & Dickman, 1999) between active states with fire propagation and an inactive state where the fire becomes irreversibly extinguished. Figure 1 shows the critical curve at the border between these two states. In the case of standard reversible phase transitions and in marked contrast to forest fire models, the state of the system can be reversibly selected by tuning the control parameter (Binder & Heermann, 2002), that is, the temperature or pressure.

In spite of the irreversible nature of the transitions, a statistical treatment of this kind of FF model reveals that they share the relevant features of many phase transitions and critical phenomena occurring under equilibrium conditions. Therefore, FF models can be described by using a well-established framework in the field of statistical physics. In fact, close to the transition point, it is well known that the correlation length among particles is quite large—diverging to infinite at the critical point (Binder & Heermann, 2002). Therefore, at the critical state $P \rightarrow P_c$, $G \rightarrow G_c$, the burning of a single tree would affect the whole forest. The onset of this collective behavior, characteristic of critical phenomena, washes out the microscopic details (i.e., the mechanisms keeping every tree alive)

Figure 1. Plot of the critical threshold G_c versus P_c . Filled circles are critical values determined quite accurately by means of epidemic simulations. The critical line (solid curve) is drawn to guide the eye. The upper part of the figure corresponds to the inactive state of the system where the fire becomes irreversibly extinguished, while the lower part corresponds to the stationary state with fire fronts.

allowing the relevant behavior of the whole system to be caught by means of a small set of simple local rules, in agreement with the concept of interacting particle systems (Liggett, 1985).

A powerful method used to characterize and study an irreversible transition consists of performing the so-called epidemic (or spreading) simulations (ES) (Grassberger, 1989). The idea behind ES is to start the simulations from a configuration very close to the inactive state and follow the temporal evolution of the system under consideration. For this purpose, a network fully occupied by trees, except for a small patch of burning trees, is employed. Depending on the values of the parameters P and G , such a small fire would either propagate or become extinguished. During the propagation the following quantities are measured:

- (i) The average number of burning trees $N(t)$;
- (ii) The survival probability of the fire $P(t)$, that is, the probability that the fire is still ignited at time t ;
- (iii) The average mean-square distance $R^2(t)$ over which the fire has spread.

Due to the existence of a diverging correlation length, it is usually assumed that the measured quantities obey simple power laws given by

$$N(t) \propto t^\eta, \quad P(t) \propto t^{-\delta} \quad \text{and} \quad R^2 \propto t^z, \quad (1)$$

where η , δ , and z are critical exponents. These exponents have been evaluated by means of extensive numerical simulations, yielding $\eta = 0.212 \pm 0.005$, $\delta = 0.459 \pm 0.005$, and $z = 1.115 \pm 0.010$ (Albano, 1995). This result allows us to place the FF model with immune trees within the universality class of directed percolation (DP) (Grassberger, 1989). It should be stressed that DP was previously proposed in the field of physics as a model for the systematic dripping of a

fluid through a lattice with randomly occupied bonds (Kinzel, 1983), and similar irreversible behavior is observed in many disciplines, such as catalysis (the interruption of chemical reactions due to the poisoning of the catalysts (Loscar & Albano, 2003)), biology (the epidemic propagation of a disease (Marro & Dickman, 1999)), ecology (the extinction of species when resources become exhausted or the environment is changed (Rozenfeld & Albano, 2001)), and sociology (models for a society of interacting individuals (Monetti & Albano, 1997)).

By introducing an additional parameter given by the lightning probability F , which can be thought of as the probability of spontaneous ignition of a tree, to the above-formulated FF model, an interesting behavior with two characteristic time scales is observed. In the limit $F \rightarrow 0$, the onset of fire is quite sporadic and occurs on large time scales. After ignition, however, fire propagates during relatively short periods of time (Drossel & Schwabl, 1992; Christensen et al., 1993; Grassberger, 1993). By analogy to sandpile models, these rapid events are called avalanches. A statistical analysis of the area of the forest reached by fire shows that it lacks a characteristic size. So, in contrast to the standard Gaussian distribution, which describes many natural phenomena exhibiting a typical (average) size, avalanches of all magnitude are expected to be observed. Under these circumstances, it is believed that the time-scale separation effectively tunes the system into a scale-free state. This behavior is the typical sign of criticality observed in studies of the phase transitions of many substances and is due to the existence of a diverging correlation length.

Finally, several attempts to reproduce forest fires in the laboratory should be mentioned. Nahmias et al. (1989, 1996) have built a square network sample containing combustible and noncombustible blocks randomly distributed with a variable concentration. The effect of randomness on the propagation of the fire is studied by considering both the presence and absence of wind. It is found that the results are consistent with critical models of percolation. Also, Zhang et al. (1992) have studied forest-fire propagation by means of paper-burning experiments. It is found that fire fronts exhibit self-affine scaling behavior that can be described by a nonlinear stochastic differential equation of the Kardar-Parisi-Zhang type with Gaussian noise.

FRACTALS

Many spatial patterns and objects in nature are either irregular or fragmented to such an extreme degree that it is very hard to describe their form. For example, the coastline of a typical oceanic island or of a continent is neither straight, nor circular, nor elliptic, and no other classical curve can serve to describe it. Similarly, there is no Euclidean surface to capture adequately the boundaries of clouds or of rough turbulent wakes. To fill this gap, Benoit Mandelbrot proposed to use a family of shapes called *fractals* for geometric representation of the shapes mentioned above and many other irregular patterns. The word *fractal* derives from the Latin *fractus* (an adjective from the verb *frangere*, meaning “to break”), capturing the irregular characteristics of geometrical objects it describes. One can think of a fractal as an irregular set consisting of parts similar to the whole. It means that a fractal is a rough or fragmented geometrical shape that can be subdivided into parts, each of which is (at least approximately) similar at reduced size to the whole. Roughness present at any resolution of a fractal object distinguishes it from Euclidean shapes. The transition from a Euclidean geometry to a fractal one reflects the conceptual jump from translational invariance of traditional Euclidean shapes to continuous scale invariance of fractal objects. The concept of fractals is useful for describing various natural objects, such as clouds, coasts, and river or road networks. However, the fractal structure of natural objects is only observed over a limited range of scales, beyond which the fractal description breaks down.

During the study of geometry of irregular patterns, it became clear that a proper understanding of irregularity or fragmentation must, among other things, involve an analysis of the intuitive notion of dimension. Topological dimension cannot properly describe strongly irregular fractal structures. Let us consider the simplest example of a fractal, namely the Cantor set, see Figure 1. For the construction of the Cantor set an iteration procedure is used. At the zeroth level, the construction of the triadic Cantor set begins with the unit interval, that is, all points on the line between 0 and 1. The first level is obtained from the zeroth one by deleting all points between $\frac{1}{3}$ and $\frac{2}{3}$, that is the middle third of the initial interval. The second level is obtained from the first level by deleting the middle third of each remaining interval at the first level. In general, the next level is obtained from the previous one by deleting the middle third of all intervals obtained from the previous level. This process continues ad infinitum. The result is a collection of points with topological dimension $d_t = 0$ since its total measure (length) is zero.

It is seen that the notion of dimension from Euclidean geometry is not very useful for the Cantor set and similar objects since it does not distinguish between the rather complex set of elements and a single point that also has a vanishing topological dimension. To cope

Figure 1. The construction of the Cantor set.

with this degeneracy, concepts of fractal dimensions were introduced for quantifying such fractal sets. Many paradoxical aspects of the Cantor set can be traced to the fact that it is dimensionally discordant. Furthermore, the discordant character of basic fractals is not at all a minor nuisance. Rather, it is such a basic feature that we shall use it to give a tentative definition of the concept of fractal. The simplest nontrivial dimension that generalizes the topological dimension is the so-called fractal dimension, which in this context can be defined as follows:

$$D_c = \lim_{n \rightarrow +\infty} \frac{\ln N_n}{\ln 1/l_n}. \quad (1)$$

Here, N_n is the number of observable elements at the n th level, l_n is the measure (length) of the smallest element at the n th level, and $1/l_n$ is the resolution. For the triangle Cantor set at the n th level, the set consists of $N_n = 2^n$ segments, each of which has length $l_n = \frac{1}{3}^n$. Therefore, the capacity dimension of the triangle Cantor set equals

$$D_c^{\text{cantor}} = \frac{\ln 2}{\ln 3} \approx 0.63. \quad (2)$$

We see that fractal dimension is noninteger. Mathematically, we can say that a fractal is a set of points whose fractal dimension exceeds its topological dimension.

Felix Hausdorff developed another way to quantify a fractal set. He suggested examining the number $N(\varepsilon)$ of small intervals needed to cover the set at a scale ε . The Hausdorff dimension is defined by considering the quantity

$$M \equiv \lim_{\varepsilon \rightarrow 0} \inf_{\varepsilon_m < \varepsilon} \sum_m \varepsilon_m^d, \quad (3)$$

which is constructed by summing d -dimensional volumes ε_m^d of balls of radii ε_m not exceeding ε that cover the fractal set. The “inf” means that all partitions of balls of radius less than ε that cover the set are considered and the one that gives the smallest possible value for the sum is kept. Hausdorff demonstrated that there is a special value D_H for the exponent d , called the Hausdorff dimension, such that for $d < D_H$ measure $M = \infty$ as $\varepsilon \rightarrow 0$ and for $d > D_H$ measure $M = 0$ in the limit $\varepsilon \rightarrow 0$.

Now the reader may ask, why do we need more than one fractal dimension? Actually, as is seen below, there is an infinite set of fractal dimensions. The reason for

this number of quantities describing a single fractal object is the *fractal form*. The form of Euclidean shapes is well described by topology. However, as was noted by Mandelbrot the concept of form possesses mathematical aspects other than topological ones. Topology is the branch of mathematics that teaches us, for example, that all pots with two handles are of the same form because, if they were made of an infinitely flexible clay, each could be molded into any new opening, closing up any old one. Obviously, this particular aspect of the notion of form is not useful in the study of individual coastlines, since it simply indicates that they are all topologically identical to each other (and to a circle). This identity is underlined by the fact that the topological dimension in each case equals 1. By way of contrast, it will be seen that coastlines of different “degrees of irregularity” tend to have different fractal dimensions. Differences in fractal dimensions express differences in nontopological aspects of form, which can be called the *fractal form*.

Now let us consider the cumulative distribution function of mass along the Cantor set. Let the initial line’s length and mass both be equal to 1, and define the cumulative distribution function for the abscissa x as being the mass contained between 0 and x . It is assumed that the total mass of the pattern is not changed while building the Cantor set. It means that we do not take away one-third of each line, but divide it in to two parts and compress them until the length of each part equals one-third of the initial line length at the previous step. Iterating this procedure up to infinity, we obtain the massive Cantor set. Because there is no mass in the intermissions, the distribution function remains constant along almost the whole length of the unit interval. However, since hammering does not affect the total mass, the distribution must manage to increase somewhere from the point of coordinates (0, 0) to the point of coordinates (1, 1). It increases over infinitely many, infinitely small, highly clustered jumps corresponding to the points of the Cantor set. The plot of the cumulative distribution function shown in Figure 2 is called the *Devil’s staircase*. It is the plot of a continuous function on the unit interval, whose derivative is 0 almost everywhere, but it rises from 0 to 1 (see Figure 2). The cumulative sums of the widths and of the heights of the steps are both equal to 1, and one finds in addition that this curve has a well-defined length equal to 2. A curve of finite length is called *rectifiable* and is of dimension $D = 1$. This example has the virtue of demonstrating that sharp irregularities do not necessarily prevent a curve from being of dimension $D = 1$, as long as they remain sufficiently few and scattered.

You can see from Figure 2 that the Devil’s staircase is a function which is not differentiable at the Cantor set points, but has zero derivative everywhere else. Because a Cantor set has measure zero, this function has

Figure 2. The Devil's staircase.

Figure 3. The Koch snowflake.

zero derivative practically everywhere and rises only on Cantor set points.

Now we consider the fractal whose dimension, in contrast to the Cantor set, exceeds unity. As an example we consider the *Koch snowflake*; see Figure 3. This is a fractal, also known as the Koch island, which was first described by Helge von Koch in 1904. It is built by starting with an equilateral triangle, removing the inner third of each side, building another equilateral triangle at the location where the side was removed, and then repeating the process indefinitely (see Figure 4). The border of the snowflake is a curve. Indeed, its area vanishes, but on the other hand each stage of its construction increases its total length by the ratio $4/3$. Thus, the limit border is of infinite length. It is also continuous, but it has no definite tangent in almost all of its points because it has, so to speak, a corner almost everywhere. Its nature borders on that of a continuous function without a derivative. This object has a fractal nature. The capacity dimension of the Koch snowflake equals $D_{\text{Koch}}^{\text{Koch}} = \ln 4 / \ln 3 \simeq 1.26$. Though the total length of the border is infinite, the area

Figure 4. The construction of the Koch snowflake.

of the Koch island originated from the initial triangle with unit side is finite and equals $S^{\text{Koch}} = 2\sqrt{5}/5$.

Fractals arising in nature usually have a more complex scaling relation than simple fractals (like the Cantor set) described above. The single fractal dimension is not enough to describe their structure, because these fractal sets usually involve a range of scales that depend on their location within the set (the simplest example is the Cantor set with some measure distributed on it). Such fractals are called *multifractals*.

The multifractal formalism is a statistical description that provides global information on the self-similarity properties of fractal objects. For practical realization of the method, one primarily covers the fractal set under study by a regular array of cubic boxes of some given mesh size l . The measure of weight p_n of a given box n is then defined as the sum of the measure of interest within the box. A simple fractal dimension α is defined by the relation:

$$p_n \sim l^\alpha. \quad (4)$$

Multifractal analysis is a generalization in which α may change from point to point and is a local quantity. The standard method to test for multifractal properties consists in calculating the moments of order q of the measure p_n defined by

$$M_q(l) = \sum_{n=1}^{n(l)} p_n^q. \quad (5)$$

Here $n(l)$ is the total number of non-empty boxes. Varying q , one can characterize the inhomogeneity of the pattern, for instance, the values of moments with large q are controlled by the densest boxes. If scaling holds, then the generalized dimension D_q is defined by the relation:

$$M_q(l) \sim l^{(q-1)D_q}. \quad (6)$$

For instance, D_0 , D_1 , and D_2 are called *capacity* (defined above), *information*, and *correlation* dimensions, respectively.

In multifractal analysis, one also determines the number $N_\alpha(l)$ of boxes having similar local scaling characterized by the same exponent α . Using it, one can introduce the multifractal singularity spectrum $f(\alpha)$ as the fractal dimension of the set of singularities of strength α according to the following relation:

$$N_\alpha(l) \sim (1/l)^{f(\alpha)}. \quad (7)$$

There is a general relationship between a moment of order q and a singularity strength α , expressed

Figure 5. Examples of Julia sets.

mathematically as a Legendre transformation:

$$f(\alpha) = q\alpha - (q-1)D_q. \quad (8)$$

Fractal sets can be impressive. For example, see Figure 5 where a number of so-called *Julia sets* is shown. (See also color plate section.)

Mathematically, the Julia set can be introduced as follows. Take some function $f(z)$ and consider the sequence obtained when $f(z)$ is iterated starting from the point $z = a$:

$$a, f(a), f(f(a)), f(f(f(a))), \text{etc.} \quad (9)$$

Depending on the initial condition a and form of the function f , it may happen that these values stay small or they do not, that is, repeatedly applying f to yield arbitrary large values. So the set of all

Figure 6. The Mandelbrot set.

numbers (initial conditions) is partitioned; into two parts, and the Julia set associated with the function f is the boundary between these sets. The “filled” Julia set includes those numbers $z = a$ for which the iterates of f applied to remain bounded. If one considers complex numbers rather than real ones, it is the complex plane that is partitioned into two sets, and the resulting picture can be quite striking; see Figure 5. That is an example of iterating a quadratic function defined in the complex plane. Linear functions do not yield interesting partitions of the complex plane, but quadratic and higher-order polynomials do.

Consider the most studied family of quadratic polynomials $f(z) = z^2 + \mu$ parametrized by a complex variable μ . As μ varies, the Julia set will vary on the complex plane. Some of these Julia sets will be connected, and some will be disconnected. Those values of μ for which the Julia set is connected are called the *Mandelbrot set* in the parameter plane. The boundary between the Mandelbrot set and its complement is often called *Mandelbrot separator curve*. The Mandelbrot set is the black shape in Figure 6 (see also color plate section). The Mandelbrot set is the set of points in the complex μ -plane that do not go to infinity when iterating the map $z_{n+1} = z_n^2 + \mu$ starting with $z = 0$. One can avoid the use of the complex numbers by substitution $z = x + iy$ and $\mu = a + ib$, and computing the orbits in the ab -plane for two-dimensional mapping:

$$\begin{aligned} x_{n+1} &= x_n^2 - y_n^2 + a, \\ y_{n+1} &= 2x_n y_n + b, \end{aligned} \quad (10)$$

with initial conditions $x = y = 0$ or equivalently $x = a$, $y = b$.

Now let us consider a natural phenomenon exhibiting fractal properties, namely, Brownian motion. Consider a fluid mass in equilibrium, for example, water in a glass; all the parts appear completely motionless. However, if one puts a small enough particle into the water, it is observed that instead of rising or descending regularly (depending on the density of the particle),

Figure 7. The example of Brownian motion of a colloidal particle.

it moves with a perfectly irregular movement. The segment of motion of a colloidal particle is presented in Figure 7 as it is seen under the microscope. The successive positions of a particle in equal time intervals are marked by points, then joined by straight lines having no physical reality whatsoever. If this particle's position were marked down 100 times more frequently, each segment would be replaced by a polygon relatively just as complicated as the whole drawing, and so on. Here, we have the natural example of the *scaling property* of the colloidal particle's motion. It is easy to see that in practice the notion of tangent is meaningless for such curves. This property of the trajectory reminds one of the Koch's snowflake described above, because when a Brownian trajectory is examined increasingly closely, its length increases without bound. Thus, we see that the trajectory of a colloidal particle has features peculiar to fractal objects, and we can qualify Brownian motion as being *fractal* and giving us a natural example of a fractal pattern.

FRAMED SPACE CURVES

The Frenet-Serret Frame

Let $\gamma: I \rightarrow \mathbb{R}^3$ be a C^3 regular parametrized space curve, with I an open interval on the real line; by regular we mean that $\gamma'(t)$ is never zero. We define the unit tangent vector $\mathbf{t} = \gamma'/|\gamma'|$ and an arclength coordinate s by $s = \int |\gamma'| dt$. An inflection point of the curve is one where $\mathbf{t}'$ is zero; away from such points, we may define the unit normal by $\mathbf{n} = \mathbf{t}'/|\mathbf{t}'|$. Then the binormal vector is $\mathbf{b} = \mathbf{t} \times \mathbf{n}$, where $\times$ denotes the cross product of vectors in $\mathbb{R}^3$.

Expressing the derivatives of these mutually orthogonal unit vectors in terms of themselves produces the Frenet equations

$$\dot{\mathbf{t}} = \kappa \mathbf{n},$$

$$\dot{\mathbf{n}} = -\kappa \mathbf{t} + \tau \mathbf{b},$$

$$\dot{\mathbf{b}} = -\tau \mathbf{n},$$

where the dot denotes derivative with respect to arclength s , and κ and τ are the *curvature* and *torsion* functions of the curve, respectively. Curvature may be defined in terms of $\mathbf{t}$ by $\kappa = |\mathbf{t}'|$, so that if κ is identically zero then $\gamma(t)$ is a straight line; more generally, inflection points, where κ vanishes, may be defined as points where the curve has at least second-order contact with a line.

We will say that a regular curve is *nondegenerate* if it has no inflection points. For such curves, we may define τ in terms of the scalar triple product as $\tau = (\mathbf{t}, \dot{\mathbf{t}}, \ddot{\mathbf{t}})/\kappa^2$. Thus, τ depends on the third derivative of γ while κ is a second-order quantity. Moreover, τ is identically zero if and only if $\gamma(t)$ lies in a fixed plane parallel to $\mathbf{t}$ and $\dot{\mathbf{t}}$.

Curvature and torsion are unchanged if we reverse the orientation of the curve (i.e., the direction of $\mathbf{t}$), or if the curve is rotated or translated within $\mathbb{R}^3$. (However, τ is changed by a minus sign if the curve is reflected, and both functions are multiplied by ρ^{-1} when the curve is scaled by a factor $\rho > 0$.) Conversely, uniqueness theorems for linear systems of differential equations, as applied to the Frenet equations, imply that two nondegenerate space curves with the same curvature and torsion, as functions of arclength, are congruent under an orientation-preserving isometry of $\mathbb{R}^3$ (congruence theorem).

Natural Frames

Although the vector $\kappa \mathbf{n}$ is well defined for any regular curve, by itself $\mathbf{n}$ is undefined at inflection points, and even at simple inflection points (where $\mathbf{t} \times \dot{\mathbf{t}}$ vanishes only to first order), κ is nondifferentiable and $\mathbf{n}$ is discontinuous. One can get around this problem and obtain a C^1 orthonormal framing along the curve, by using *natural frames*, also known as relatively parallel adapted frames (Bishop, 1975). Such frames satisfy

equations of the form

$$\begin{aligned}\dot{\mathbf{t}} &= k_1 \mathbf{m}_1 + k_2 \mathbf{m}_2, \\ \dot{\mathbf{m}}_1 &= -k_1 \mathbf{t}, \\ \dot{\mathbf{m}}_2 &= -k_2 \mathbf{t},\end{aligned}\quad (1)$$

where $\mathbf{t}$ is the usual unit tangent vector, $\mathbf{m}_1$ is a unit normal to $\mathbf{t}$, $\mathbf{m}_2 = \mathbf{t} \times \mathbf{m}_1$, and k_1, k_2 are the *natural curvatures*. The natural frame is not unique, but any two such frames for the same oriented curve differ only by rotating $\mathbf{m}_1$ and $\mathbf{m}_2$ around $\mathbf{t}$ through an angle which is constant along the curve.

Any regular curve that is C^k for $k \geq 2$ has a C^{k-1} natural frame. When the curve also has a Frenet frame, and we suppose $\mathbf{n} = \cos \theta \mathbf{m}_1 + \sin \theta \mathbf{m}_2$, then $k_1 = \kappa \cos \theta$, $k_2 = \kappa \sin \theta$, and $\theta = \int \tau \, ds$. Thus, a space curve is planar when its natural curvatures (k_1, k_2) , when graphed in $\mathbb{R}^2$, lie along a fixed line through the origin. More generally, a space curve lies on a fixed sphere of radius ρ when (k_1, k_2) lie along a line distance $1/\rho$ from the origin.

The above congruence theorem is true for regular curves with degeneracies when suitably rephrased in terms of natural frames and natural curvatures.

The Hasimoto Correspondence

The vortex filament flow

$$\frac{\partial \gamma}{\partial t} = \frac{\partial \gamma}{\partial x} \times \frac{\partial^2 \gamma}{\partial x^2} \quad (\text{VFF})$$

is an evolution equation for space curves that models the self-induced motion of a vortex filament in an ideal fluid taking only local effects into account. This model, originally formulated by L. Da Rios in 1906 (Ricca, 1996), is also known as the *localized induction approximation*. Note that if x is an arclength parameter at a given time, then it remains so for all t . We will take x as such, and then the right-hand side of (VFF) is $\kappa \mathbf{B}$ when expressed in terms of the Frenet frame.

Hasimoto (1972) showed that solutions to this equation induce solutions to the focusing cubic nonlinear Schrödinger equation

$$iq_t + q_{xx} + \frac{1}{2}|q|^2 q = 0, \quad (\text{NLS})$$

by virtue of letting

$$q = \kappa e^{i\theta} \quad \text{with} \quad \theta = \int \tau \, ds. \quad (\text{H})$$

However, the “constant of integration” cannot be taken to be an arbitrary function of t ; in fact, substituting (H) into (NLS) shows that we must have $\theta_t = \kappa^{-1} \dot{\kappa} - \tau^2 + \frac{1}{2} \kappa^2$. Thus, $q(x, t)$ is unique up to multiplication by a unit modulus constant. Unfortunately, definition (H) for the Hasimoto map

does not work at points of inflection (unless $\dot{\kappa}$ vanishes to the same order as κ). However, it may be defined for arbitrary regular curves by using the natural curvatures of an evolving natural frame (see Calini, 2000, Section 1.4), whereupon $q = k_1 + ik_2$.

DNA and White’s Formula

At its lowest level of structure, DNA consists of two right-handed helices connected by base pairs, resembling the rungs of a twisted ladder. At lesser magnification the double helix, seen as a single strand, usually coils around itself in a left-handed fashion called *negative supercoiling*. Moreover, as the base pairs are separated during DNA replication and the ladder is untwisted, the supercoiling relaxes (becomes less negative) or may even reverse itself to become positive supercoiling. The dynamic interplay of these two levels of structure in DNA is governed by White’s formula (White, 1970; Pohl, 1980). Although the formula, as stated below, applies only to closed loops of DNA (which occur in bacteria and in the mitochondria of some cells), it also governs the behavior of long strands of DNA, since in living cells the DNA is clamped to a protein scaffold at intervals of roughly 100,000 base pairs (Cozzarelli, 1992).

Let $\mathcal{C} \subset \mathbb{R}^3$ be a closed oriented regular curve and let $\mathbf{v}$ be a C^1 unit normal vector field along $\mathcal{C}$. (In DNA, we should regard $\mathcal{C}$ as one of the helices and $\mathbf{v}$ as pointing along the base pairs.) Let $\tilde{\mathcal{C}} = \mathcal{C} + \varepsilon \mathbf{v}$ have the same orientation. For $\varepsilon > 0$ sufficiently small, the linking number $\text{Lk}(\mathcal{C}, \tilde{\mathcal{C}})$ is independent of ε and will be denoted by Lk . Define the total twist of $\mathbf{v}$ by the integral

$$\text{Tw} = \frac{1}{2\pi} \int (\mathbf{t}, \mathbf{v}, \dot{\mathbf{v}}) \, ds.$$

The twisting of $\mathbf{v}$ about γ obviously contributes to $\text{Lk}(\mathcal{C}, \tilde{\mathcal{C}})$, but there is also a contribution independent of $\mathbf{v}$, due to the “writhe” of $\mathcal{C}$ about itself.

White’s formula says that

$$\text{Lk} = \text{Tw} + \text{Wr},$$

where Wr is the *writhe* of $\mathcal{C}$, defined as follows. On $D = \{(x, y) \in \mathcal{C} \times \mathcal{C} | x \neq y\}$, define the vector-valued function $\mathbf{e} = (x - y)/|x - y|$. Extend $\mathbf{e}$ continuously to the two components of ∂D , as the forward- and backward-pointing unit tangent vector. Then

$$\text{Wr} = \frac{1}{4\pi} \int \frac{\mathbf{e}^* \, d\mathbf{S}}{\bar{D}},$$

where $d\mathbf{S}$ is the standard element of area on the unit sphere S^2 and $\bar{D}$ is the closure of D . If s_1 and s_2 are arclength parameters on D , then we may also write

$$\text{Wr} = \frac{1}{4\pi} \int \int \left(\mathbf{e}, \frac{\partial \mathbf{e}}{\partial s_1}, \frac{\partial \mathbf{e}}{\partial s_2} \right) ds_1 ds_2.$$

When C is nondegenerate and $\mathbf{v} = \mathbf{n}$, the Frenet normal, Lk is called the *self-linking* or *helicity* of C , and White's formula specializes to

$$SL(C) = Wr + \int \tau \, ds,$$

a formula which was discovered much earlier by Calagareanu and later extended to regular closed curves (Pohl, 1980).

In DNA, with each base pair twisting the ladder by about 34° , Tw is positive and on the order of 10^5 . The fact that DNA supercoiling is left-handed is reflected by a negative value of Wr , leading to a relatively small overall linking number. However, this number is rarely zero; the surgery that unlinks each of the two strands, a necessary step in cell division, is accomplished by enzymes known as *topoisomerases* (Summers, 1995).

FRANCK-CONDON FACTOR

The concept of Franck-Condon transitions between electronic energy levels originates from the Born-Oppenheimer approximation, which adiabatically separates the fast electronic degrees of freedom of a molecule from the much slower nuclear degrees of freedom (since the nuclei are much heavier than the electrons, electronic motions occur as if the nuclei were fixed in place). Within the Born-Oppenheimer approximation, the total wave function $\Psi(q, Q)$ can be written as a product of an electronic and a nuclear (vibrational)

wave function:

$$\Psi(q, Q) = \Psi^{(el)}(q; Q) \varphi^{(vib)}(Q), \quad (1)$$

where the electronic wave function $\Psi^{(el)}(q; Q)$ depends only parametrically on the nuclear coordinates Q . One first calculates the electronic eigenstates for a particular nuclear configuration Q , which is assumed to be fixed in space, and assembles electronic potential energy surfaces by varying the nuclear coordinates Q step-by-step. The nuclear wave function is subsequently calculated by solving the Schrödinger equation on these potential energy surfaces, assuming that the electrons can adapt adiabatically to a changing nuclear configuration.

As usual, the intensity of a transition between two electronic states k and l with vibrational quanta n and m is given by the transition dipole matrix element

$$\mu_{kn,lm}^2 = \langle \Psi_{k,n} | \hat{\mu} | \Psi_{l,m} \rangle^2 = \left(\frac{\partial \mu}{\partial q} \right)^2 \langle \Psi_{k,n} | \hat{q} | \Psi_{l,m} \rangle^2. \quad (2)$$

When incorporating the product wave function of Equation (1), we obtain

$$\mu_{kn,lm}^2 = \left(\frac{\partial \mu}{\partial q} \right)^2 \langle \Psi_k^{(el)} | \hat{q} | \Psi_l^{(el)} \rangle^2 \langle \varphi_{k,n}^{(vib)} | \varphi_{l,m}^{(vib)} \rangle^2. \quad (3)$$

The transition dipole matrix element separates into a product because (a) the transition dipole operator $\partial \mu / \partial q \cdot \hat{q}$ acts on the electronic coordinates q only and (b) we have assumed that the transition dipole operator does not depend on the nuclear coordinate Q (*Franck-Condon approximation*). The second term $\langle \varphi_{k,n}^{(vib)} | \varphi_{l,m}^{(vib)} \rangle^2$ is the *Franck-Condon factor*.

Figure 1a shows possible transitions between two electronic potential energy surfaces (S_0 and S_1). At not too high temperatures, only the vibrational ground state $v=0$ in the electronic ground state S_0 will be populated. When both potential energy surfaces have the same shape and their lowest points are not displaced, the Franck-Condon factors $\langle \varphi_n^{(vib)} | \varphi_m^{(vib)} \rangle^2$ reduce to the condition of orthonormality of the vibrational eigenstates (i.e., the vibrational wave functions are the same on both potential energy surfaces). Hence, in that case, only the $v=0 \rightarrow v'=0$ transition (the *zero-phonon transition*) carries oscillator strength, while all others are dark. However, when both potential energy surfaces are displaced (i.e., the excited state has a different nuclear coordinate to the ground state), the absorption spectrum will consist of a series of absorption lines (a Franck-Condon progression) as depicted in Figure 1b. The intensity of these lines scales with the Franck-Condon factors $\langle \varphi_{k,n}^{(vib)} | \varphi_{l,m}^{(vib)} \rangle^2$. In the spectra of Figure 1b, the energy origin relates to the frequency of the zero-phonon transition, and

Figure 1. (a) Displaced potential energy surfaces of the electronic ground state S_0 and the first electronic excited state S_1 with the possible transitions depicted at a temperature of 0 K. The overlap integrals $\langle \varphi_i^{(\text{vib})} | \varphi_j^{(\text{vib})} \rangle^2$ of the vibrational wave functions in both electronic states determine the strength of the individual absorption lines. (b) Absorption spectra for Huang–Rhys parameters $S = 0.5$ and 2, respectively.

the energy spacing between the various lines is given by the frequency ω of the oscillator. We call normal modes with such a displacement of the potential energy surfaces Franck–Condon active modes.

An analytic expression for the Franck–Condon factors can be given when the potential energy surfaces are assumed to be harmonic (as in Figure 1a):

$$\begin{aligned} V_{S_0} &= \frac{1}{2} \hbar \omega Q^2, \\ V_{S_1} &= E_{01} + \frac{1}{2} \hbar \omega Q^2 - \bar{x} \hbar \omega Q, \end{aligned} \quad (4)$$

where Q is the dimensionless oscillator coordinate, E_{01} the energy separation between the electronic ground and first excited states at $Q = 0$, and ω the vibrational frequency. The dimensionless displacement $\bar{x}$ between potential energy surfaces is a measure of the strength of the coupling between electronic and vibrational transition. It is common to introduce an alternative coupling parameter, the Huang–Rhys parameter:

$$S \equiv \frac{x^2}{2} \quad (5)$$

with which the Franck–Condon factors can be expressed as (Fitch, 1968)

$$\langle \varphi_{S_1,n}^{(\text{vib})} | \varphi_{S_0,m}^{(\text{vib})} \rangle^2 = e^{-S} \frac{m!}{n!} S^{n-m} [L_m^{n-m}(S)]^2, \quad (6)$$

where $L_j^{i-j}(S)$ are the Laguerre polynomials. For the important case where $T = 0$ K, the only occupied initial level is $m = 0$ and $L_0^n(S) = 1$, and we obtain

$$\langle \varphi_{S_1,n}^{(\text{vib})} | \varphi_{S_0,0}^{(\text{vib})} \rangle^2 = \frac{S^n}{n!} e^{-S}. \quad (7)$$

For $S < 1$, the zero phonon line is the most intense transition, while for larger displacements, $S > 1$, the intensity is shifted toward transitions with higher vibrational quanta on the electronically excited state S_1 (Figure 1b). This finding can be explained in simple words with the Franck–Condon principle, which states that in a classical picture, an electronic transition occurs very quickly and is most likely to occur without changes in the positions of the nuclei. Hence, the transition is vertical from the bottom of the S_0 potential energy surface to the S_1 surface. The quantum mechanical formulation of this principle is that the intensity of a vibronic transition is proportional to the square of the overlap integral between the vibrational wave functions of the two states that are involved in the transition.

The concept of a Franck–Condon transition was originally formulated for electronic states. However, it can be used in a more general sense and appears whenever an adiabatic separation of timescales can be made between two molecular degrees of freedom. For example, this is the case when a high-frequency vibrational mode is coupled to a low-frequency vibrational mode. In that case, $\Psi^{(\text{el})}$ in the expressions above is replaced by the wave function of the high-frequency mode, but the rest of the formalism remains unchanged. Most prominent examples are hydrogen bonds $\text{XH} \cdots \text{Y}$, where the high-frequency X–H stretching vibration is coupled to the low-frequency $\text{XH} \cdots \text{Y}$ hydrogen bond vibration. One of the striking features of hydrogen bonds is an extraordinarily large anharmonic coupling between both modes that leads to a Franck–Condon-like progression in the absorption spectrum of the X–H stretching band.

FREDHOLM THEOREM

The Fredholm theorem gives a necessary and sufficient condition for the existence of a solution to a linear equation of the form $A\mathbf{x} = \mathbf{y}$, where A is a linear operator and $\mathbf{x}$ and $\mathbf{y}$ are vectors. Consider the matrix

$$A = \begin{pmatrix} 1 & 4 & 5 \\ 2 & 5 & 7 \\ 3 & 6 & 9 \end{pmatrix}, \quad (1)$$

and the linear map $\mathcal{F}$, which associates the vector $A\mathbf{x}$ to each vector $\mathbf{x}$ in $\mathbb{R}^3$. If x_i , $i = 1 \dots 3$, are the

components of $\mathbf{x}$, we have

$$\begin{aligned}\mathcal{F}\mathbf{x} = A\mathbf{x} &= x_1 \begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix} + x_2 \begin{pmatrix} 4 \\ 5 \\ 6 \end{pmatrix} + x_3 \begin{pmatrix} 5 \\ 7 \\ 9 \end{pmatrix} \\ &= (x_1 + x_3) \begin{pmatrix} 1 \\ 2 \\ 3 \end{pmatrix} + (x_2 + x_3) \begin{pmatrix} 4 \\ 5 \\ 6 \end{pmatrix}.\end{aligned}\quad (2)$$

The third equality comes from the fact that the last column of A can be written as the sum of its first two columns. It is then clear that the equation $\mathcal{F}\mathbf{x} = \mathbf{y}$ has a solution if and only if $\mathbf{y}$ is a linear combination of the first two columns of A . In this case, there is more than one solution because the kernel or null space of A is not trivial.

If we equip $\mathbb{R}^3$ with the inner product $\langle \mathbf{x}, \mathbf{y} \rangle = \sum_{i=1}^3 x_i y_i$, the transpose A^T of A , defined by $\{A^T\}_{ij} = \{A\}_{ji}$, is such that

$$\langle A\mathbf{x}, \mathbf{v} \rangle = \langle \mathbf{x}, A^T \mathbf{v} \rangle, \quad (3)$$

for any two vectors $\mathbf{x}$ and $\mathbf{v}$ in $\mathbb{R}^3$. This equality shows that $\mathbf{v}$ is orthogonal to the range of A (i.e., $\langle A\mathbf{x}, \mathbf{v} \rangle = 0$ for every $\mathbf{x}$ in $\mathbb{R}^3$) if and only if $\mathbf{v}$ is in the kernel of A^T ; that is, $A^T \mathbf{v} = \mathbf{0}$. As a consequence, the existence of a solution to the equation $\mathcal{F}\mathbf{x} = \mathbf{y}$ (i.e., $A\mathbf{x} = \mathbf{y}$), which is equivalent to $\mathbf{y}$ being in the range of A , can be restated as $\mathbf{y}$ being orthogonal to the kernel of A^T . This is the contents of the Fredholm theorem, which is often presented as the following alternative theorem.

Fredholm alternative: For a matrix A , either the equation $A\mathbf{x} = \mathbf{y}$ always has a solution or the kernel of A^* is nontrivial. Here A^* is the adjoint of A , which is its transpose (resp. Hermitian transpose) if A has real (resp. complex) entries. The Fredholm alternative can be stated in a similar fashion for a special class of infinite-dimensional linear operators. In this case, $A = \lambda I - \mathcal{L}$, where $\mathcal{L}$ is a compact operator, λ is a nonzero complex number, and I is the identity operator (see for instance Reed & Simon, 1980; Kreyszig, 1989; Dunford & Schwartz, 1988).

Applications of this theorem involve multiple scales analysis and perturbation theory. Assume for instance that we want to solve the eigenvalue problem $\mathcal{L}\mathbf{x} = \lambda\mathbf{x}$, where the linear operator $\mathcal{L}$ can be written as $\mathcal{L} = \mathcal{L}_0 + \varepsilon\mathcal{L}_1$ and ε is a small parameter. If we look for expansions of the eigenvector $\mathbf{x} = \mathbf{x}_0 + \varepsilon\mathbf{x}_1 + \dots$ and eigenvalue $\lambda = \lambda_0 + \varepsilon\lambda_1 + \dots$ in powers of ε , substitute in the equation, and equate the left- and right-hand sides at each power of ε , we obtain a hierarchy of linear equations of the form

$$(\mathcal{L}_0 - \lambda_0 I)\mathbf{x}_i = \mathcal{J}_i, \quad i = 0, 1, \dots, \quad (4)$$

where I is the identity operator and the right-hand side, $\mathcal{J}_i$, of (4) only depends on $\mathbf{x}_k$ for $k < i$.

In particular, $\mathcal{J}_0 = \mathbf{0}$ and $\mathcal{J}_1 = \lambda_1 \mathbf{x}_0 - \mathcal{L}_1 \mathbf{x}_0$. At each step of this iterative process, the linear equation $(\mathcal{L}_0 - \lambda_0 I)\mathbf{x}_i = \mathcal{J}_i$ has a solution if and only if $\mathcal{J}_i$ is orthogonal to the kernel of the adjoint of $\mathcal{L}_0 - \lambda_0 I$. This typically gives the value of the coefficient λ_i of the expansion of the eigenvalue λ in powers of ε . Once λ_i is known, one can then solve the equation $(\mathcal{L}_0 - \lambda_0 I)\mathbf{x}_i = \mathcal{J}_i$ for $\mathbf{x}_i$. A similar method can be applied to solve equations of the form

$$\mathcal{L}\mathbf{x} = \mathcal{G}(\mathbf{x}), \quad (5)$$

where $\mathcal{L} = \mathcal{L}_0 + \varepsilon\mathcal{L}_1$ and $\mathcal{G}$ is a nonlinear function of $\mathbf{x}$. Such equations are often encountered in bifurcation theory. Assume for instance that $\mathcal{G}$ is polynomial, say $\mathcal{G} = \langle \mathbf{x}, \mathbf{x} \rangle \mathbf{x}$, and that one knows a solution $\mathbf{x}_0$ to the linear equation $\mathcal{L}_0 \mathbf{x}_0 = \mathbf{0}$. Small-amplitude solutions to the nonlinear problem can be approximated by introducing a small parameter that measures the size of $\mathbf{x}$ and rescaling. For instance, the scaling $\mathbf{x} = \sqrt{\varepsilon} \mathbf{y}$ turns (5) into $(\mathcal{L}_0 + \varepsilon\mathcal{L}_1) \mathbf{y} = \varepsilon \langle \mathbf{y}, \mathbf{y} \rangle \mathbf{y}$. A solution of the form $\mathbf{y} = \mathbf{y}_0 + \varepsilon \mathbf{y}_1 + \dots$ can then be sought, using an iterative process similar to the one discussed above.

FREE ENERGY

The concept of “free energy” is a key concept to characterize physically relevant states in statistical mechanics (see, e.g., Mandl, 1988; Reichl, 1998). Given an equilibrium system of statistical mechanics with energy levels E_i of the microstates i , the (Helmholtz) free energy F is defined as

$$F(\beta) = -\frac{1}{\beta} \log Z(\beta), \quad (1)$$

where

$$Z(\beta) = \sum_i e^{-\beta E_i} \quad (2)$$

is the partition function and β is the inverse temperature. Apparently, the free energy is different from the internal energy U given by

$$U = -\frac{\partial}{\partial \beta} \log Z(\beta) = \langle E_i \rangle. \quad (3)$$

The difference is given by the entropy S times the absolute temperature T :

$$F = U - TS. \quad (4)$$

This equation can also be regarded as describing a Legendre transformation from U to F . Equilibrium states minimize the free energy (rather than the internal energy)—in this sense F is more relevant than U . The minimum of F can be achieved in two contrasting ways, either by making the internal energy U small, or by making the entropy S large (or both). Changes of the free energy are related to the maximum amount of work a system can do at constant pressure and temperature.

The basic principle underlying statistical mechanics, the maximum entropy principle, can also be formulated as a “principle of minimum free energy” (Beck & Schlögl, 1993). In this formulation, one starts from fixed intensive quantities (e.g., the inverse temperature β) and considers a free energy function $F[p]$ as a function of an a priori arbitrary set of probabilities $[p] = \{p_1, p_2, \dots\}$. The probabilities p_i can describe any state, for example, also non-equilibrium and nonthermal states. One then requires

$$F[p] = \sum_i p_i E_i + \beta^{-1} p_i \log p_i = U - \beta^{-1} S \quad (5)$$

to have a minimum in the space of all possible probability distributions. This minimum is achieved for the canonical distribution

$$p_i = \frac{1}{Z} e^{-\beta E_i}. \quad (6)$$

There are straightforward generalizations of this principle for systems with several intensive quantities, for example, grand canonical ensembles.

For nonlinear dynamical systems, the concept of free energy is often seen in a much broader sense. Various generalized types of free energies can be defined. A key ingredient for this more general approach is the so-called thermodynamic formalism of dynamical systems (Beck & Schlögl, 1993). One defines partition functions that contain information on certain fluctuating quantities associated with the dynamical system, for example, local singularities of the invariant density or local Lyapunov exponents. To proceed to a (formal) statistical mechanics description, one then defines a free energy function for these partition functions quite analogous to Equation (1).

Examples are “static,” “dynamic,” and “expansion” free energies of dynamical systems, as well as the so-called “topological pressure.” Let us here consider the static free energy in somewhat more detail. This free energy function contains information on the spectrum of singularities of the invariant density of the dynamical system and is closely related to very important quantities that characterize multifractals, the so-called Rényi dimensions. One covers the attractor (or repeller) under consideration with small d -dimensional cubes (“boxes”) of volume ε^d , where d is an integer

dimension large enough to embed the attractor. The static partition function is then defined as

$$Z(\beta) = \sum_i p_i^\beta = \sum_i e^{-\beta \alpha_i V}, \quad (7)$$

where p_i is the invariant probability measure associated with box i and β is a formal “inverse temperature” parameter. To illustrate the similarities with statistical mechanics, we have written in the above equation $p_i =: \varepsilon^{\alpha_i} = e^{-\alpha_i V}$, where α_i is like a fluctuating energy associated with each box i and $V = -\log \varepsilon$ plays the role of a formal volume variable. One can then study the free energy density associated with this partition function,

$$f(\beta) := \lim_{V \rightarrow \infty} -\frac{1}{\beta V} \log Z(\beta). \quad (8)$$

This static free energy, up to a trivial factor, is indeed identical with the Rényi dimensions D_β :

$$f(\beta) = \frac{\beta - 1}{\beta} D_\beta. \quad (9)$$

In this way, methods borrowed from statistical mechanics play an important role for the statistical description of dynamical systems.

While the above generalized free energies, of relevance for nonlinear dynamical systems, have only formal analogies with conventional free energies, a more fundamental generalization of statistical mechanics suitable for complex systems has been suggested by Tsallis (1988). In this so-called non-extensive statistical mechanics approach (Abe & Okamoto, 2001; Kaniadakis et al., 2002), the entire formalism of statistical mechanics is generalized by starting from more general entropy measures, the Tsallis entropies. These are defined by

$$S_q = \frac{1}{q-1} \left(1 - \sum_i p_i^q \right). \quad (10)$$

Here the p_i are probabilities associated with the microstates i of a physical system. Note that the Tsallis entropies look somewhat similar to the Rényi information measures but are indeed different (there is no logarithm). The parameter q , called “entropic index,” can take on any real value but is in practice often close to 1. For $q \rightarrow 1$, one can easily check that the Tsallis entropies reduce to the ordinary Shannon entropy $S_1 = -\sum_i p_i \log p_i$. The principal idea of non-extensive statistical mechanics is to do everything we know from ordinary statistical mechanics, but start from the more general entropy measures. Naturally, ordinary statistical mechanics is contained as a special case ($q = 1$) in this more general formalism.

The maximum entropy principle yields power-law generalizations of the canonical ensemble,

$$p_i = \frac{1}{Z_q(\beta)} (1 + (q-1)\beta E_i)^{-1/(q-1)}, \quad (11)$$

which reduce to Equation (6) for $q \rightarrow 1$. As a consequence, there is then also a more general free energy $F_q(\beta)$, which is parametrized by the entropic index q . One can basically show that the entire formalism of thermodynamics has simple q -generalizations, for example, for the generalized free energy there is a relation of the form

$$F_q = U_q - TS_q, \quad (12)$$

where the index q indicates that the q -generalized canonical ensemble is chosen. This type of formalism has interesting physical applications, for example, for fully developed turbulence and for scattering processes in high-energy physics (Beck, 2002).

FREE PROBABILITY THEORY

A new probabilistic context emerged in the 1980s (Voiculescu, 1985) from studies in operator algebras, a mathematical subject with ties to quantum physics. Free probability theory (FPT) is developing along a parallel to the basics of usual probability theory, drawn from assumptions designed for quantities with the highest degree of noncommutativity. FPT has turned out to have important connections to random matrix theory (Voiculescu, 1991) as well as to some combinatorics (Speicher, 1998) and to certain models in physics (Voiculescu, 1997).

To introduce FPT, one takes the view that “a probability theory” deals with expectation values $\varphi(a)$ for the elements a , called random variables, of a set A endowed

with operations of addition, multiplication, and multiplication by scalars. We may describe FPT as noncommutative probability theory (i.e., the products ab and ba can be different for $a, b \in A$) with independence defined by a new relation called free independence. In usual probability theory, A consists of numerical functions on some space of events and clearly $ab = ba$ in this case. By contrast, noncommutative probability occurs typically when A consists of quantum mechanical observables Q . These are linear operators on a vector space $\mathcal{H}$ with an inner product $\langle \cdot, \cdot \rangle$ and $\varphi(Q) = \langle Q\xi, \xi \rangle$ where $\xi \in \mathcal{H}$ is a fixed vector with $\langle \xi, \xi \rangle = 1$. Under quantum mechanics, the usual definition of independence of Q_1 and Q_2 requires commutation $Q_1 Q_2 = Q_2 Q_1$ and $\varphi(f(Q_1)g(Q_2)) = \varphi(f(Q_1))\varphi(g(Q_2))$ for polynomials f and g . Free independence of Q_1, Q_2 , by contrast requires that

$$\varphi(\dots f(Q_1)g(Q_2)h(Q_1)\dots) = 0 \quad (1)$$

whenever

$$\begin{aligned} \dots, \varphi(f(Q_1)) &= 0, \varphi(g(Q_2)) = 0, \\ \varphi(h(Q_1)) &= 0, \dots, \end{aligned} \quad (2)$$

where $\dots, f, g, h, \dots$ are polynomials and Q_1, Q_2 alternate as arguments. The definition of free independence extends to sets of variables by replacing the one-variable polynomials $f, g, h, \dots$ by corresponding polynomials in noncommuting variables from those sets. Note that if Q_1, Q_2 satisfy free independence, then in most cases $Q_1 Q_2 \neq Q_2 Q_1$.

The FPT analogue of the central limit theorem (Voiculescu, 1985; Voiculescu et al., 1992) states $\varphi(Q_j) = 0, \varphi(Q_j^2) = 1$ and $|\varphi(Q_j^k)| \leq C_k$, then

$$S_n = n^{-1/2}(Q_1 + \dots + Q_n) \quad (3)$$

will have in the limit, the moments of a semicircle distribution, that is,

$$\lim_{n \rightarrow \infty} \varphi(S_n^k) = (2\pi)^{-1} \int_{-2}^2 t^k (4 - t^2)^{1/2} dt. \quad (4)$$

Many other topics in classical probability theory have FPT analogs. The list includes the following (Voiculescu et al., 1992; Biane & Speicher, 1998; Voiculescu, 2002):

- Addition and multiplication of freely independent random variables corresponds to highly nonlinear free convolution operations on the distributions.
- The FPT infinitely divisible laws and stable laws have been classified, and there are corresponding processes with free increments.
- Semicircular processes are the FPT analog of Gaussian processes, and in particular there is a concept of free Brownian motion.
- There are stochastic integrals with respect to free Brownian motion.

- There is a free entropy theory that deals with FPT analogues of Shannon's differential entropy and of the Fisher information.

The semicircle distribution, which plays the role of the Gauss law in FPT, was well known from Wigner's work as the limit-distribution of eigenvalues of large symmetric random matrices with independent identically distributed Gaussian entries (the Gaussian orthogonal ensemble). The explanation of this surprising coincidence was found to be that free independence often occurs asymptotically among large random matrices (Voiculescu, 1991). For instance, if for each n we are given two sets $\{A_1^{(n)}, \dots, A_m^{(n)}\}$ and $\{B_1^{(n)}, \dots, B_p^{(n)}\}$ of $n \times n$ Hermitian random matrices, then the requirement that their joint distribution (as matrix-valued random variables) be the same as that of $\{UA_1^{(n)}U^{-1}, \dots, UA_m^{(n)}U^{-1}, B_1^{(n)}, \dots, B_p^{(n)}\}$ for all unitary matrices U is the key to asymptotic free independence of the two sets (Voiculescu, 1998). For $n \times n$ random matrices T , the expectation functional is $\varphi_n(T) = n^{-1}E(\text{Tr}T)$, where E denotes the expectation of the numerical random variable $\text{Tr}T$. Asymptotic free independence means the equalities of free independence hold after taking the limit $n \rightarrow \infty$.

A random matrix T is thus a classical matrix-valued random variable and at the same time a noncommutative random variable. Passing to the noncommutative context discards information about the entries, since the expectation values $\varphi_n(T^k)$ remember only the eigenvalue distribution of T .

Asymptotic free independence results for random matrices imply that their limit behavior is governed by FPT. For instance, for the sum or product of random matrices satisfying free independence asymptotically, the limit distribution of eigenvalues is computed by the free convolution operations.

Among the simplest cases of asymptotic free independence are a pair of independent matrices from the Gaussian ensembles or a constant matrix and one from a Gaussian ensemble. Also, if X_n is a rectangular $[an] \times n$ Gaussian random matrix with independent and identically distributed (i.i.d.) entries, then $X_n^*X_n$ and a constant $n \times n$ random matrix will exhibit asymptotic free independence. Besides these simplest instances of asymptotic free independence, there are many others involving unitary matrices, random permutation matrices or matrices with non-Gaussian i.i.d. entries (Voiculescu, 2000). Also, Gaussian random band-matrices can be handled with more involved FPT techniques (Shlyakhtenko, 1996). Most asymptotic free independence results for complex Hermitian or unitary matrices also hold for real symmetric or orthogonal matrices. The differences between distributions of eigenvalue spacings between the real and complex cases occur at another scale,

which is wiped out by taking the limit of the φ_n as $n \rightarrow \infty$.

FPT methods have also been used for physics models related to asymptotics of random matrices, like the large N Yang–Mills two-dimensional quantum chromodynamics in papers of I.M. Singer, R. Gopakumar and D. Gross, and M. Douglas (Voiculescu, 1997). Also occurring in physics are multimatrix-models, corresponding to ensembles of k -tuples of $N \times N$ -matrices with the densities $c_N \exp(-N \text{Tr}P(T_1, \dots, T_k))$ that have connections to the analog of entropy in FPT (Voiculescu, 2002). An indication about where FPT and quantum field theory connect is given by the combinatorial approach to FPT (Speicher, 1998) that deals with non-crossing partitions of $\{1, \dots, n\}$, that is, with planar Feynman diagrams.

FRENKEL–KONTOROVA MODEL

In 1938, Yakob Frenkel and Tatiana Kontorova developed in some detail a model originally proposed by Ulrich Dehlinger (see Nabarro, 1967) for studying stationary dislocations in a crystal, and its motion. A perfect crystalline (regular lattice) solid subjected to small deformations returns to a perfect lattice arrangement of atoms after the forces causing the deformations are released. This regime of small

deformations is called “elastic.” Larger deformations can lead to rearrangements of the crystal lattice. In this other regime, called “plastic,” the perfect lattice is not restored after tension is released. The attempt to describe the energetics involved in those irreversible rearrangements (or lattice dislocations, see Figure 1(b)) led to the posing of a theoretical physics problem of a discrete elastic one-dimensional field of displacements (atomic positions) experiencing a spatially periodic potential (Dehlinger, 1929; Frenkel & Kontorova, 1939; Frank & Van der Merwe, 1949). Figure 1(c) shows a schematic representation of Dehlinger’s *Verhakung* (interlocking), as he named his idea.

The Frenkel–Kontorova (FK) model has been used for modeling nanostructural properties of adsorbed monolayers of atoms on crystalline surfaces, nonlinear magnetic excitations in magnets, ionic conductors, and many other solid-state physics problems. Today it has become a textbook mathematical model with direct applications in condensed matter, statistical physics, nonlinear fields, and material science, often under different names, notably the “discrete sine-Gordon” or “periodic Klein–Gordon” equation.

The Generalized Frenkel–Kontorova Model

In the generalized FK model, a discrete one-dimensional field (u_n) ($-\infty < n < +\infty$), has a potential energy density

$$H(u_{n+1}, u_n) = KV(u_n) + W(\Delta u_n), \quad (1)$$

where $W(\Delta u)$ is the interaction between neighbor components of the field, $V(u)$ is a periodic function $V(u+1) = V(u)$, and K is a parameter controlling the relative strength of both (V and W) contributions to the energy density.

The standard version of the model corresponds to the simplest choices of sinusoidal on-site potential V and harmonic spring interaction W :

$$V = \frac{1}{(2\pi)^2} [1 - \cos(2\pi u)],$$

$$W(\Delta u) = \frac{1}{2} (\Delta u)^2 - \sigma \Delta u, \quad (2)$$

where σ is the unstretched length of the spring, the value at which W is a minimum.

Keeping V as above, the following choice for W

$$W = \frac{1}{(2\pi)^2} [1 - \cos(2\pi(\Delta u - \gamma))] \quad (3)$$

(known as a “chiral XY model” in a magnetic field) models a system of magnetic moments with strong planar (XY) anisotropy (here described by the angles $2\pi u_n$), with chiral (preferred relative angle γ)

Figure 1. (a) Schematic net outcome of a plastic deformation. Relative shift between layers does not occur uniformly: The slip process can take place sequentially by the mechanism of dislocation motion shown in (b). (c) Dehlinger’s picture of the imperfection, that he named *Verhakung*, where the atoms of the upper row, in this displacement, experience a periodic potential on account of their interaction with atoms in the lower row.

interactions W , and K in Equation (1) measuring the intensity of the external magnetic field. Other choices are motivated by different physical situations of interest.

To complete the formal definition of the generalized FK model, one must define its time evolution and this choice depends on the specific application one has in mind. The standard model with Hamiltonian dynamics

$$\frac{d^2 u_n}{dt^2} = u_{n+1} - 2u_n + u_{n-1} - \frac{K}{2\pi} \sin(2\pi u_n) \quad (4)$$

corresponds to the simplest discretized version of the integrable partial differential equation known as sine-Gordon (SG):

$$\frac{d^2 u}{dt^2} = \frac{d^2 u}{dx^2} - \sin(2\pi u). \quad (5)$$

This justifies the name of “discrete SG model” often used for the FK model.

Some physical applications, for example, in Josephson junction devices, suggest introducing dissipative terms in Equation (4) (involving first-time derivatives $\dot{u}_n$) and more complicated functional forms of the right-hand-side dependence on u_n and u_{n+1} . The richness of dynamical behaviors shown by the different dynamical FK models is a continuing source of interest in both theory development and applications (Braun & Kivshar, 1998, 2004; Floría & Mazo, 1996).

The Equilibrium Problem for Convex FK Models

A simpler problem, but quite complex, is the characterization of equilibrium properties of the generalized FK model. The physical motivation for studying this problem comes mainly from the observed abundance of modulated phases in minerals and man-made materials

and compounds, and the need to understand the peculiar multiphase diagrams shown by experimental studies.

For the case in which W is not a convex function, like the chiral XY example above, the difficulties of a complete rigorous characterization of equilibria are much greater than in the case of convex W interaction. For the latter, Aubry's work allowed a satisfactory theory in the infinite system size (thermodynamic) limit, by showing a one-to-one correspondence between equilibrium configurations (u_n), which satisfy the (force-equilibrium) equations

$$\frac{\partial(H(u_n, u_{n-1}) + H(u_{n+1}, u_n))}{\partial u_n} = 0 \quad (6)$$

and orbits of a symplectic twist map of the cylinder.

When an equilibrium configuration is such that any segment of length $L = M - N + 1$, ($u_N, \dots, u_M$), can only increase its energy as result of arbitrary fluctuations of $u_{N+1}, \dots, u_{M-1}$, the field configuration is called a minimum energy configuration (MEC).

There are two types of MEC, which are both recurrent—meaning that given any integer p and any number $\varepsilon > 0$, there are integers m and $q > 0$ such that both inequalities: $|u_{p+q} - u_p - m| < \varepsilon$ and $|u_{p+q+1} - u_{p+1} - m| < \varepsilon$ are satisfied. These two types of recurrent MEC are called commensurate (or periodic) phases and incommensurate (or quasi-periodic) phases, respectively. Remarkably, there are nonrecurrent MECs, which are rigorous discrete versions of the soliton solutions of continuous partial differential equations (like the integrable sine-Gordon model). These are called “discommensurations” or “homoclinic field configurations,” and they correspond to the original motivation (Dehlinger's *Verhakung*) of the FK model: localized dislocations over the recurrent (periodic or quasi-periodic) substrate phase.

Commensurate Phases

These are periodic configurations with rational p/q average spacing ω (defined as $\lim_{L \rightarrow \infty} (u_M - u_N)/L$), where $u_{n+p} - q = u_n$. Such field configurations are generically pinned, meaning that one has to put some finite energy E_{PN} on the system to displace the configuration over the path-dependent barriers of energy (called “Peierls–Nabarro barriers”) separating configurations that are equivalent by translations σ_{mn} .

A pinned configuration has a finite coherence length (or decay range) ξ of fluctuations, meaning that if a field component (the center u_{n_0}) is kept displaced by an external force, the rest of components u_n are displaced with exponentially decaying amplitude $\exp(-|n - n_0|/\xi)$. Also, the linear spectrum of small oscillations (phonon spectrum) of a pinned configuration has a finite gap $\Delta > 0$.

Incommensurate or Quasi-periodic Phases

Recurrent configurations with irrational average spacing ω can be viewed as limits of sequences of periodic phases of mean spacing $\omega_n \rightarrow \omega$ as $n \rightarrow \infty$. The physical properties of these structures depend on the parameter K of the model: For each irrational ω there is a critical value $K_c(\omega)$ such that:

- For $K < K_c$, the quasi-periodic MEC is sliding (unpinned), so that $E_{PN} = 0$. Consequently, localized induced fluctuations extend through the system so that the decay range diverge, $\xi \rightarrow \infty$. The spectrum of phonons of a sliding configuration is gapless, $\Delta = 0$. The distribution function of the fractional parts $\text{Frac}(u_n)$ in this phase is a continuous function.
- For $K > K_c$, the incommensurate phase is pinned, $E_{PN} > 0$, the decay range is finite, and a gap Δ appears in the phonon spectrum. The distribution function of the values $\text{Frac}(u_n)$ is now a Cantor function; there are infinitely many forbidden intervals (gaps) of values of the field (modulo 1).

MacKay (1993) has characterized this drastic change in the physical properties of quasi-periodic fields as a critical phenomenon (already called by Aubry as a “transition by breaking of analyticity”) using renormalization group methods for the case of noble irrational ω and the standard model (2).

Discrete Solitons (DSs) or Discommensurations (DCs)

Field configurations can connect asymptotically ($n \rightarrow \pm \infty$) two commensurate configurations (usually one is a translation of the other, though they can be different in general) by an energy minimizing path of exponentially localized length (the width of the DS) around a lattice site (the center of the DS). The width is of the order of the decay range ξ of the recurrent (periodic) substrate.

These structural defects are the elementary excitations of the modulated phase, or localized compressions (advanced DCs) or expansions (retarded DCs) superimposed on the regular substrate modulation. If ω is close to a rational ω_0 , the modulated phase corresponding to a mean spacing ω can be correctly described as an array of localized DCs (advanced if $\omega > \omega_0$, retarded if $\omega < \omega_0$) over a periodic substrate of mean spacing ω_0 . The interaction energy between neighboring DCs decays exponentially with the quotient interdistance/width, $\exp(-1/(\xi|\omega - \omega_0|))$, so that for ω very close to ω_0 and/or high values of the pinning parameter K (ξ small), the elementary excitations are almost non-interacting (and pinned). However, at lower values of K the tail overlapping of the DCs makes the interactions strong enough, and the array of strongly interacting DCs becomes sliding.

Though with less rigorous formal basis, the DC theory of modulated phases is a well-established formal description of equilibrium for nonconvex FK models. In these cases, interactions between DCs can be of either (attractive or repulsive) sign and even alternating with interdistance. Also, the inner structure of DC can be more complex than in the convex case.

FREQUENCY DOUBLING

Frequency doubling, or second-harmonic generation, is the process in which an intense laser beam propagating through a nonlinear optical medium produces light at double the frequency of the input beam (Bloembergen, 1969; Boyd, 2002; Shen, 1984; Zernike & Midwinter, 1973). It was the first laser-induced nonlinear optical effect to be reported, and its observation by Franken et al. (1961) marked the beginning of the field of nonlinear optics. This work involved the use of ruby laser radiation at 694.3 nm propagating through a quartz crystal to produce second-harmonic radiation at 347.2 nm (Franken et al., 1961).

Our laboratory demonstration of second-harmonic generation is shown in Figure 1 (also in color plate section). The 800 nm radiation of a titanium-doped sapphire laser is converted into the second harmonic at 400 nm in passing through a lithium niobate crystal. A prism is used to separate the second harmonic from the fundamental radiation exiting of the crystal. A side view showing the ray trajectories is represented in Figure 1c. We can see the red light of the laser beam illuminating the crystal and the blue light of the second harmonic exiting the crystal, together with

some portion of unconverted red light. Typically, not all of the incident radiation is converted into the second harmonic. The quantity describing the effectiveness of converting the incident radiation into a harmonic is called the conversion efficiency.

The physical origin of the process of second-harmonic generation can be understood as follows. The electric field of a monochromatic optical wave incident upon a nonlinear medium forces the electrons bound in atoms and molecules to oscillate about their equilibrium positions. Thus, it induces a polarization (dipole moment per unit volume) in the medium that depends on the strength of the electric field. This polarization plays the role of a secondary source of electromagnetic radiation.

The Lorentz model, which treats the atom as a harmonic oscillator, provides a good description of the linear atomic response. The electric force F_E exerted on the electron by the electromagnetic field displaces the electron with respect to the nucleus. The restoring force F_{rest} has the opposite action, tending to return the electron to its equilibrium position. If the applied field is weak, the restoring force is linear with respect to the electron displacement x from equilibrium, that is,

$$F_{\text{rest}} = -m\omega_0^2 x.$$

Here m is the mass of the electron and ω_0 is the resonance frequency of the oscillator. Therefore, the potential energy function of the medium is quadratic with respect to x (see Figure 2a, the solid line):

$$U = - \int F_{\text{rest}} dx = \frac{1}{2} m\omega_0^2 x^2.$$

The parabolic shape of the potential energy function describes harmonic oscillations of the electron at the applied optical field frequency. In such a way, the induced polarization gives rise to the radiation at the applied field frequency. Figure 2b shows the waveform of the incident monochromatic electromagnetic wave of frequency ω (the top graph). For the case of a medium with linear response, there is no distortion of the waveform associated with the polarization of the medium (the middle graph).

In order to describe the nonlinear response, the model has to be extended by allowing the possibility of a nonlinearity in the restoring force (Boyd, 2002). The lowest-order nonlinear response is modelled by adding a contribution quadratic in the displacement so that

$$F_{\text{rest}} = -m\omega_0^2 x - max^2.$$

Here a characterizes the strength of the nonlinearity. The potential energy function of such a system has an additional term that is cubic with respect to x (Figure 2a, the dashed line):

$$U = -\frac{1}{2} m\omega_0^2 x^2 + \frac{1}{3} max^3.$$

Figure 1. Second-harmonic generation in lithium niobate: (a) Experimental setup; (b) close-up view of the observation screen; (c) side view showing ray trajectories.

Because of the nonlinearity of the restoring force, the atomic response can show a harmonic distortion of the waveform associated with polarization oscillation (Figure 2b the bottom graph). In this case, the induced polarization will give rise to radiation not only at the same frequency as the applied field, but also at higher frequencies (harmonics) as well. A nonlinear effect can occur only if the applied field is sufficiently strong to produce a large displacement x .

More formally, the nonlinear response of a medium to a strong incident field can be described by a nonlinear susceptibility (Bloembergen, 1969; Boyd, 2002; Shen, 1984). In the case of a linear response to the applied field, the induced polarization P depends linearly upon the electric field strength E according to the relationship

$$P = \chi^{(1)} E, \quad (1)$$

where the constant of proportionality $\chi^{(1)}$ is the linear susceptibility. In the case of a nonlinear response, optical response can be described by expanding polarization P as a power series in the field strength E :

$$P = \chi^{(1)} E + \chi^{(2)} E^2 + \chi^{(3)} E^3 + \dots \quad (2)$$

The quantities $\chi^{(2)}$ and $\chi^{(3)}$ represent the second- and third-order nonlinear optical susceptibilities, respectively. Here, we will consider only the second-order nonlinear response.

Second-order nonlinear interactions can occur only in noncentrosymmetric media. A typical value of the second-order nonlinear susceptibility in crystals is $\chi^{(2)} \simeq 5 \times 10^{-8}$ esu (6.3×10^{-7} SI). We refer to

$$P^{(2)} = \chi^{(2)} E^2 \quad (3)$$

Figure 2. (a) Potential energy function in case of linear response (solid line) and nonlinear noncentrosymmetric response (dashed line); (b) polarization waveforms associated with the atomic response.

as the second-order nonlinear polarization. The strength of the applied optical field can be represented by

$$E = E_0 \exp^{-i\omega t} + \text{c.c.} \quad (4)$$

Substituting (4) into the equation for the second-order nonlinear polarization (3), we can obtain

$$P^{(2)} = 2\chi^{(2)} E E^* + (\chi^{(2)} E^2 \exp^{-i2\omega t} + \text{c.c.}). \quad (5)$$

We can see from (5) that the second-order polarization consists of a constant contribution (the first term) and a contribution at frequency 2ω (the second term). This doubled frequency contribution leads to the generation of radiation at the second-harmonic frequency 2ω .

Frequency doubling can also be understood by means of a virtual energy level description (Figure 3) (Boyd, 2002). The diagram shows that for a lossless

Figure 3. Energy-level diagram describing second-harmonic generation.

medium, the creation of a photon at a doubled frequency 2ω must be accompanied by the destruction of two photons at frequency ω , or according to Manley–Rowe relations: the rate at which a photon at frequency 2ω is created is equal to the rate at which two photons at frequency ω are destroyed.

Second-harmonic generation is a process in which the initial and final quantum mechanical states (energy levels) are identical. Therefore, the energy conservation and momentum conservation laws need to be satisfied. According to the momentum conservation law, the momentum of the two incident photons of frequency ω , $2\hbar\mathbf{k}_\omega$, must be equal to the momentum of the radiated photon of frequency 2ω , $\hbar\mathbf{k}_{2\omega}$:

$$2\hbar\mathbf{k}_\omega = \hbar\mathbf{k}_{2\omega}. \quad (6)$$

Here $\mathbf{k}_\omega$ and $\mathbf{k}_{2\omega}$ are the wave vectors of the incident wave and the second harmonic, respectively. According to (6), in order for the second-harmonic generation to effectively occur, it is necessary for the following phase matching condition to be satisfied:

$$2\mathbf{k}_\omega = \mathbf{k}_{2\omega}. \quad (7)$$

The dispersion relation for light propagating in a medium is

$$\mathbf{k}_\omega = n(\omega) \frac{\omega}{c}, \quad (8)$$

where $n(\omega)$ is the index of refraction for the wave of frequency ω . Thus, condition for perfect phase matching with collinear beams (7) requires that

$$n(\omega) = n(2\omega). \quad (9)$$

In practice, the condition of perfect phase matching is often difficult to achieve because the refractive index of materials displays an effect of normal dispersion: $n(\omega)$ increases monotonically with ω . Thus, condition (9) cannot be satisfied.

There are several ways to achieve phase matching. One of the most common ways is to use the birefringence displayed by many crystals. Birefringence is the

dependence of the refractive index on the direction of polarization of the optical radiation. In order to achieve phase matching through the use of birefringent crystals, the highest-frequency wave (2ω) should be polarized in the direction that gives it the lower of two possible refractive indices. There is another technique, known as quasi-phase matching, that can be used when normal phase matching cannot be implemented (Armstrong et al., 1962; Boyd, 2002). This technique involves the use of periodically poled materials, that are fabricated so that the orientation of one of the crystalline axis is inverted periodically as a function of position within the material. It results in periodic alternation of the sign of $\chi^{(2)}$, that can compensate for a nonzero wave vector mismatch $\Delta\mathbf{k}$.

Second-harmonic generation can usefully convert the coherent output of a fixed-frequency laser to a different spectral region (Zemike & Midwinter, 1973). For example, the infrared radiation of an Nd:YAG laser operating at 1064 nm can be converted into 532 nm visible radiation with a conversion efficiency of more than 50%.

FRÖHLICH THEORY

Starting in the late 1960s and continuing until his death in 1991, Herbert Fröhlich developed a theory of biological coherence that was based on quantum interactions between dipolar constituents of biomolecules. Fröhlich advocated momentum-space correlations within a living system such as a membrane, a cell, or an organism. This dynamic order would be a characteristic feature that distinguishes living systems from inanimate matter. The key assumptions

Figure 1. Illustration of the Fröhlich model.

of Fröhlich's theory can be listed as follows:

- (i) a continuous supply of metabolic energy (also referred to as energy pumping) above a threshold level,
- (ii) the presence of thermal noise due to physiological temperature,
- (iii) internal organization of the biosystem that promotes functional features,
- (iv) the existence of a large transmembrane potential difference, and
- (v) a nonlinear interaction between two or more types of degrees of freedom.

As a result of these nonlinear interactions, in addition to the global minimum that characterizes a biological system in its nonliving state, a metastable energy minimum is achieved in the living state.

The Fröhlich model of biological coherence is based on a condensate of quanta of collective polar vibrations. It is a non-equilibrium property due to the interactions of the system with both the surrounding heat bath and an energy supply (see Figure 1). The energy is channeled into a single collective mode that becomes strongly excited. Most importantly, the Fröhlich model relies on the nonlinearity of internal vibrational mode interactions and in this respect is somewhat reminiscent of the laser action principle. Associated with this dynamically ordered macroscopic quantum state is the emergence of polarization due to the ordering of dipoles in biomolecules such as membrane head groups. Furthermore, Fröhlich predicted the generation of coherent modes of excitation such as dipole oscillations in the microwave frequency range. Nonlinear interactions between dynamic degrees of freedom were predicted to result in the local stability of the polarized state and in the long-range frequency-selective interactions between two systems with these properties.

In the search for empirical support of this model, Fröhlich placed an emphasis on the presence of dipole moments in many biomolecular systems that would then oscillate in synchrony in the frequency range of $10^{11} - 10^{12}$ Hz due to their nonlinear interactions. Con-

sequently, due to the resonant dipole-dipole coupling in a narrow frequency range, the entire biological system can be seen as a giant oscillating dipole. An alternative picture developed within the Fröhlich theory was that of a Bose-Einstein condensation in the space of dipole oscillations. The Hamiltonian postulated by Wu and Austin (1977) takes the form

$$\begin{aligned}
 H = & \sum_i \omega_i a_i^\dagger a_i + \sum_i \Omega b_i^\dagger b_i + \sum_i \Theta_i P_i^\dagger P_i \\
 & + \frac{1}{2} \sum_{i,j,k} (\chi a_i^\dagger a_j b_k^\dagger + \chi^* a_j a_i^\dagger b_k) \\
 & + \sum_{i,j} (\lambda b_i a_j^\dagger + \lambda^* b_i^\dagger a_j) \\
 & + \sum_{i,j} (\xi P_i a_j^\dagger + \xi^* P_i^\dagger a_j), \quad (1)
 \end{aligned}$$

where $(a_i^\dagger, a_i)$, $(b_i^\dagger, b_i)$, and $(P_i^\dagger, P_i)$ are the cell, heat-bath, and energy-pump creation and annihilation (boson-type) operators, respectively. A kinetic rate equation was derived for this model that indicates Bose-type condensate in the frequency domain with a stationary occupation number dependence of the dipole modes given by

$$N_i = \left[e^{\beta(\omega_i - \mu)} - 1 \right]^{-1}. \quad (2)$$

The nonlinear coupling comes from the dipole-phonon interaction proportional to χ . Provided that the oscillating dipoles are within a narrow band of resonance frequencies ($\omega_{\min} \leq \omega_i \leq \omega_{\max}$) and the coupling constants (χ , λ and ξ) are large enough, long-range ($\sim 1 \mu\text{m}$) attractive forces are expected to act between the dipoles.

The effective potential between two interacting dipoles which initially vibrate with frequencies ω_1 and ω_2 is given by

$$U(r) = \frac{E}{r^3} + \frac{F}{r^6}. \quad (3)$$

The van der Waals coefficient F is negative (attractive) unless the average distance between the interacting particles is very short. However, the van der Waals attraction between particles rapidly decreases with distance making it an unlikely candidate mechanism for biological coherence. The coefficient E can be both positive (repulsion) and negative (attraction) depending on the occupation of the new eigenstates of the system. Population inversion leads to attraction while thermal equilibrium for occupation numbers leads to repulsion between particles. In particular, E is given by

$$E = \frac{\hbar e^2 Z |\bar{A}| \gamma}{4\bar{\omega} M} \left(\frac{1}{\epsilon'(\omega_+)} - \frac{1}{\epsilon'(\omega_-)} \right), \quad (4)$$

where M is the mass of a dipole, e is the electron charge, Z is the number of elementary charges on each dipole, A is an angle constant, and $\epsilon'(\omega)$ is the real part of the frequency-dependent dielectric constant. The quantities $\omega_{\pm}$ are the new dipole vibration frequencies

$$\omega_{\pm} = \left[\frac{1}{2}(\omega_1^2 + \omega_2^2) \pm \left(\frac{1}{4}(\omega_1^2 - \omega_2^2)^2 + \frac{\beta_0^4}{(\epsilon'_{\pm})^2} \right)^{1/2} \right]^{1/2}, \quad (5)$$

where $\beta_0 = \gamma^2 e^2 \sqrt{Z_1 Z_2} / M r^3$. In the resonant frequency case, the effective interaction energy between two oscillating dipoles was found to be long-range, depending on distance as r^{-3} .

Most of the expected condensation of dipolar vibrations was envisaged by Fröhlich to take place in the cell membrane due to its strong potential on the order of 10–100 mV across the thickness of 5–10 nm giving an electric field intensity of $1\text{--}20 \times 10^6$ V/m. The resultant dipole-dipole interactions were calculated to show a resonant long-range order at a high-frequency range of $10^{11}\text{--}10^{12}$ Hz with a propagation velocity of about 10^3 m/s. In addition to membrane dipoles, several other candidates for Fröhlich coherence were considered, including double ionic layers, dipoles of DNA and RNA molecules, and plasmon oscillations of free ions in the cytoplasm.

Applications of the Fröhlich theory were made to explain cancer proliferation, where a shift in the resonant frequency was seen to affect the cell-cell signaling, the brain waves, and enzymatic chemical reactions.

Various experiments have been reported that appeared to demonstrate the sensitivity of metabolic processes to certain frequencies of electromagnetic radiation above the expected Boltzmann probability level. Raman scattering experiments by Webb (1980) found non-thermal effects in *E. coli* but these could not be reproduced by other labs. Irradiation of yeast cells by millimeter waves showed increased growth at specific frequencies (Grundler, et al., 1983). Rouleaux formation of human erythrocytes was explained in terms of Fröhlich's resonant dipole-dipole attraction (Paul et al., 1983) but did not rule out standard coagulation processes. While some of these experiments illustrate nonthermal effects in living matter that would require nonlinear and non-equilibrium interactions for explanation, no unambiguous experimental proof has been furnished to date to support Fröhlich's hypothesis.

It is interesting to note that while Fröhlich sought evidence for frequency selection in biological systems, another famous physicist, Alexander S. Davydov tried to find spatial localization of vibrational energy in biological systems such as DNA and peptides. There is a conceptual link between these two approaches as shown

by Tuszyński et al. (1983) that involves self-focusing in reciprocal (Fröhlich) or real space (Davydov).

FRUSTRATION

Frustration is the inevitable consequence of trying to simultaneously satisfy a number of conflicting constraints. In general, when faced with such conflicting requirements one's only way out is to compromise. Inevitably, there are usually many widely different ways to compromise, some better than others. In physical systems, frustration arises from competition between different contributions to the total energy of a system. Generally, each contribution can be separately minimized by a unique choice of state but the different contributions have different minimum-energy states. The presence of frustration then typically leads to a situation in which there are many, very different, states with similar low energies separated from one another by "barriers" of much higher energy states. This leads to a proliferation of low-energy dynamical modes in the system and, especially in the presence of disorder, slow (glassy) dynamics.

A simple physical example that shows the way in which frustration leads to complexity is afforded by the Ising model (See **Spin systems**). Each site of a regular lattice bears a simple binary variable—a spin than can

Figure 1. The ground state configuration of the 2-d Ising model on a square lattice.

point either up or down. The energy of the whole system has a contribution from each bond on the lattice. A given bond contributes an energy $+J$ if the spins at either end of the bond point in the same direction and an energy $-J$ if they point in opposite directions (this corresponds to the anti-ferromagnetic Ising model). First, consider the model on a two-dimensional square lattice with N sites (this model was solved exactly by Lars Onsager in 1940) as shown in Figure 1.

We can divide the lattice into two sub-lattices such that each site on one sub-lattice is surrounded entirely by sites on the other sub-lattice. The lowest energy state of the system is trivially found—we make all the spins on one sub-lattice point in one direction and all the spins on the other sub-lattice point in the opposite direction (clearly there are two such states with the same energy related by global inversion of all the spins). Each bond of the lattice connects two oppositely oriented spins so that the total energy is $-2NJ$. Any other configuration of spins must result in at least $4J$ bonds connecting like spins and so has energy $\geq -2NJ + 4J$. This situation is simple and unfrustrated—all bonds can be simultaneously “happy.”

Now consider the same simple model, with the same rules for assigning energy, but on a triangular lattice as shown in Figure 2. It is fairly simple to see that there is no way of simultaneously making all the bonds happy. Each elementary plaquette of the lattice has three spins, each of which wants to be in a different state to its neighbors—at least one bond must be unsatisfied (i.e., have energy $+J$). The minimum energy states of this system have alternate “stripes” of aligned spins so that each plaquette has only one unsatisfied bond giving a minimum energy of $-NJ$. A little thought will tell one that there are six equivalent configurations with this minimum energy: three choices for the direction of the stripes as well as the possibility of reversing all spins.

A very simple situation in which there is geometrical frustration arises when one considers the adsorption of one material onto a surface of a different material. Sup-

Figure 2. One of the degenerate ground state configurations of the 2-d Ising model on a triangular lattice.

pose that we have a substrate of material A, which is flat, and we deposit atoms of material B onto it. Further suppose that a bulk sample of pure A atoms has a lattice parameter a , while a bulk sample of pure B atoms has a lattice parameter b . When only a few atoms of material B have been deposited, they will simply bond with A atoms at the surface. Once a large number of B atoms have been deposited, they will begin to come into contact and be able to bond with each other. In the case that $b \approx a$, there is no frustration—the B atoms simply attach themselves to surface A atoms and quite happily bond to other B atoms when they are adjacent. This happy situation is referred to as epitaxial growth and happens for the technologically important situation in which material A is the semiconductor gallium arsenide and material B is the alloy aluminium gallium arsenide. However if $b \neq a$, then the growth of B is frustrated—there is a competition between the desire of the B atoms to attach themselves to A atoms and their desire to be a distance b from the nearest B atom. If the energetics are such that one set of bond energies is much greater than the other, the system will either form an adsorbed, strained layer, with B-B neighbor distance set by the substrate (a) or it will detach itself entirely. If the energetics are more closely balanced, then the system will find a compromise, often involving the formation of dislocations in the surface layer. There are, of course, many ways of introducing such dislocations to relieve the strain. A simple model for this effect was proposed by Frenkel and Kontorova (See **Frenkel-Kontorova model**).

An interesting system in which the frustration can be continuously tuned experimentally is the Josephson junction array (See **Josephson junction arrays**). This is a system composed of a lattice of superconducting islands separated by weak links. Each island is characterized by a phase variable and the total energy of the array can be written

$$E = -\varepsilon J \sum_{(i,j)} \cos(\theta_i - \theta_j - A_{ij}),$$

where the sum is over nearest-neighbor sites, θ_i is the phase on the i th island, ε_j is the Josephson energy, and A_{ij} is a twist variable along a nearest-neighbor bond. The twist variables must satisfy

$$\sum \Phi_{ij} = 2\pi \frac{\Phi}{\Phi_0},$$

where the sum is around all the bonds on an elementary plaquette of the lattice, Φ is the magnetic flux through that plaquette, and Φ_0 is the flux quantum $h/2e$. When the flux per plaquette is an integer number of flux quanta, the system is unfrustrated and its ground state simply has all phases equal. When Φ/Φ_0 is a rational fraction, the system is uniformly frustrated and its ground states exhibit periodic spatial ordering. If Φ/Φ_0 is irrational (or, in finite-sized systems if the commensuration length exceeds the system size), then the system exhibits complex, aperiodic ordering. The introduction of frustration introduces a greater range of elementary excitations and a greater degeneracy in the lowest energy states.

Spin glasses are magnetic alloys in which there are competing interactions between magnetic ions that can be of either sign. The canonical model of a spin glass was devised by S.F. Edwards and P.W. Anderson (Edwards & Anderson, 1975) in which each site of a regular lattice bears a classical vector spin. Nearest-neighbor pairs of spins interact via an exchange coupling drawn from a quenched (i.e., nondynamical) random distribution that includes both ferromagnetic and antiferromagnetic possibilities. The energy of a given configuration of spins is then given by

$$E = - \sum_{(i,j)} J_{ij} \mathbf{S}_i \cdot \mathbf{S}_j.$$

The combination of frustration and quenched randomness leads to very rich behavior. A mean field version of this model in which all pairs of spins interact weakly was proposed by Sherrington and Kirkpatrick (1975) and solved by Parisi (1979) by introducing the notion of replica symmetry breaking. An alternative approach based on an equation (the so-called TAP equation) for the number of metastable states was presented by Thouless, Anderson, and Palmer (Mezard et al., 1987; Fischer & Hertz, 1991). The relevance of the notions developed for this mean field model to real finite range spin glasses (the EA model) has been questioned and the so-called droplet picture for these was developed (Fischer & Hertz, 1991). The debate over the relative merits of the droplet picture and the broken replica symmetry picture has resurfaced recently and is still highly contentious. Irrespective of which detailed picture is correct, it is clear that the combination of frustration and quenched randomness leads to spin glass systems having many, closely competing low-energy configurations. This leads to a hierarchy of free energy val-

leys and barriers causing the dynamics of these systems to show very complex and slow dynamical behavior such as aging in which the dynamical response of the system depends on its thermal history. Much current attention is focussed on quantum mechanical frustrated systems both regular (spin liquid states in quantum antiferromagnets) and disordered (quantum spin glasses, etc.).

FUNCTION SPACES

There are classes of spaces that, while maintaining some essential features of the n -dimensional Euclidean space ($\mathbb{R}^n$), are still general enough to include spaces of functions as particular examples. This entry covers both these abstract classes and some particular function spaces.

A *metric space* retains only the notion of distance. To be a metric on a space X , $d(x, y)$ should be nonnegative and satisfy

- (i) $d(x, x) = 0$ for every $x \in X$;
- (ii) $d(x, y) = d(y, x)$ for every $x, y \in X$; and
- (iii) the triangle inequality: $d(x, y) \leq d(x, z) + d(z, y)$ for every x, y , and $z \in X$.

More precisely, it is the pair (X, d) , rather than X alone, that is the metric space. For $x, y \in \mathbb{R}^n$, the standard metric is just given by $d(x, y) = |x - y|$.

A metric leads to a notion of convergence: $x_j \rightarrow x$ in X as $j \rightarrow \infty$ if for any $\varepsilon > 0$, there is an N such that $d(x_j, x) < \varepsilon$ whenever $j \geq N$. In Euclidean spaces, a sequence converges if and only if it is a Cauchy sequence. In the context of a metric space, $\{x_j\}_{j=1}^\infty$ is Cauchy if for any $\varepsilon > 0$, there exists an N such that $d(x_i, x_j) < \varepsilon$ whenever $i, j \geq N$. A metric space

in which every Cauchy sequence converges is called *complete*.

The general version of a length is a norm. Consider a real (or complex) vector space X [which satisfies the property: if x and y are elements of X , then so is $x + \lambda y$ for any $\lambda \in \mathbb{R}$ (or $\mathbb{C}$)]. Then a norm on X is a nonnegative function $\|\cdot\|$ such that

- (iv) $\|x\| \geq 0$ with equality if and only if $x = 0$;
- (v) $\|\lambda x\| = |\lambda| \|x\|$ for every $x \in X$ and $\lambda \in \mathbb{R}$ (or $\mathbb{C}$); and
- (vi) $\|x + y\| \leq \|x\| + \|y\|$ for every $x, y \in X$ (the triangle inequality again).

Note that X needs to be a vector space so that if x and y are in X , so are λx (as in (v)) and $x + y$ (as in (vi)). The pair $(X, \|\cdot\|)$ is called a *normed space*. A complete normed space is called a *Banach space*.

Given a norm, the distance between x and y , $d(x, y) = \|x - y\|$, defines a metric; thus, normed spaces are less general than metric spaces.

The standard notion of the length of a vector in $\mathbb{R}^n$ is not just an ad hoc definition satisfying (iv)–(vi). Vectors are specified relative to n orthogonal coordinate axes, and the expression for the length follows from Pythagoras's theorem. Since the mathematical formalization of orthogonality involves the dot product ($x \cdot y = \sum_{j=1}^n x_j y_j$), it is natural to consider generalizing this concept.

An *inner product space* is a real (or complex) vector space X equipped with an inner product: that is, a function (x, y) that associates a real (or complex) number with any two elements $x, y \in X$ and satisfies

- (vii) $(x, x) \geq 0$, with equality if and only if $x = 0$;
- (viii) $(x, y) = (y, x)$ for all $x, y \in X$; and
- (ix) $(\lambda x + \mu y, z) = \lambda(x, z) + \mu(y, z)$ for every $x, y, z \in X$ and every $\lambda, \mu \in \mathbb{R}$ (or $\mathbb{C}$).

A complete inner product space is called a *Hilbert space*.

Due to (vii), it is possible to set $\|x\| = (x, x)^{1/2}$; the Cauchy–Schwarz inequality

$$|(x, y)| \leq \|x\| \|y\|, \quad (1)$$

a consequence of (vii)–(ix), can then be used to show that $\|\cdot\|$ is a norm on X . Thus, every inner product space can also be viewed as a normed space, implying that inner product spaces are more restrictive than normed spaces.

There is one abstract setting that includes all the above: the only concept retained is the notion of an open set. Such *topological spaces* (Sutherland, 1975) consist of a space X and a topology $\mathcal{T}$ —the collection of all the open sets in X . This collection must satisfy:

- (x) $\emptyset$ and X are elements of $\mathcal{T}$;

- (xi) if $O_1, O_2 \in \mathcal{T}$, then $O_1 \cap O_2 \in \mathcal{T}$; and
- (xii) the union of any collection of sets in $\mathcal{T}$ is also in $\mathcal{T}$.

Any metric space gives rise to a topological space by taking $\mathcal{T}$ to be the collection of all of its open sets, but there are some notions of convergence (e.g., weak convergence, See **Functional analysis**) that do not correspond to any choice of metric. Because of this, topological vector spaces (vector spaces equipped with a topology) form the basis of advanced functional analysis (Rudin, 1991).

We now give some simple examples of function spaces, in which I denotes any interval (finite or infinite) in $\mathbb{R}$.

The space $C^0(I)$ consists of all real-valued continuous functions on I . The standard norm on this space is the supremum or uniform norm $\|\cdot\|_\infty$, defined as

$$\|f\|_\infty = \sup_{x \in I} |f(x)| \quad (2)$$

(essentially the maximum value of f on the interval I , provided that this is attained). Since the uniform limit of continuous functions is itself continuous, equipped with the uniform norm $C^0(I)$ is complete, and so a Banach space. For functions defined on the whole real line, such uniform convergence is often too strong. More realistic is uniform convergence on compact intervals, that is, equivalent to convergence in the metric

$$d_K(f, g) = \sum_{j=1}^{\infty} 2^{-j} \times \min \left(\sup_{x \in [-j, j]} |f(x) - g(x)|, 1 \right) \quad (3)$$

which cannot be derived from a norm.

The space $C^k(I)$ consists of all continuous functions whose first k derivatives are also continuous,

$$C^k(I) = \{f \in C^0(I) : d^j f / dx^j \in C^0(I), \\ j = 1, \dots, k\}. \quad (4)$$

Its standard norm (which makes C^k a Banach space) is formed by adding the maximum value of f and its first k derivatives,

$$\|f\|_{C^k} = \sum_{j=0}^k \|d^j f / dx^j\|_\infty. \quad (5)$$

The theory of generalized functions uses the space $\mathcal{D}(\mathbb{R})$ of infinitely differentiable functions with compact support in $\mathbb{R}$ ("test functions"). A sequence $\{\phi_n\}_{n=1}^\infty \subset \mathcal{D}(\mathbb{R})$ converges to ϕ in $\mathcal{D}$ if there is a fixed compact set K containing the support of each ϕ_n , and $d^j \phi_n / dx^j$ converges uniformly to $d^j \phi / dx^j$ for every

$j = 0, 1, 2, \dots$. This form of convergence gives rise to a topology, but there is no corresponding metric.

Another family of Banach spaces are the “Lebesgue spaces” $L^p(I)$, consisting of all Lebesgue integrable functions on I for which the L^p norm defined by

$$\|f\|_{L^p} = \left(\int_I |f(x)|^p dx \right)^{1/p}, \quad 1 \leq p < \infty, \\ = \left\{ \begin{array}{l} \inf\{M : |f(x)| \leq M \text{ almost everywhere in } I\}, \\ p = \infty \end{array} \right. \quad (6)$$

is finite. (See Priestley (1997) for a readable introduction to Lebesgue integration.) The space $L^2(I)$ of square integrable functions is a Hilbert space: for two functions $f, g \in L^2(I)$ one can define an inner product by setting

$$(f, g) = \int_I f(x) \overline{g(x)} dx. \quad (7)$$

Note that this is a very natural space of functions to consider physically: if $u(x)$ denotes a velocity then the L^2 norm of $u(x)$ is proportional to the kinetic energy.

The modern theory of partial differential equations relies heavily on *Sobolev spaces* (Adams, 1975; Evans, 1998; Gilbarg & Trudinger, 1983). These allow discussion of the degree of differentiability of functions that are only weakly differentiable: a function f defined on an open interval I has weak derivative $Df = g$ if there is a function $g \in L^1(I)$ such that for every infinitely differentiable function ϕ with compact support in I

$$\int_I g(x) \phi(x) dx = - \int_I f(x) \phi'(x) dx. \quad (8)$$

(The right-hand side would be the result of integrating $\int f'(x) \phi(x) dx$ by parts if f were a C^1 function. Although this is similar to the definition of the derivative of a generalized function, the weak derivative must be an element of L^1 .) By requiring successive weak derivatives $D^j f$ to be in $L^p(I)$, we obtain the Sobolev space $W^{k,p}(I)$:

$$W^{k,p}(I) = \{f \in L^p(I) : D^j f \in L^p(I), \\ j = 1, \dots, k\}. \quad (9)$$

Given the norm

$$\|f\|_{W^{k,p}} = \left(\sum_{j=0}^k \|D^j f\|_{L^p}^p \right)^{1/p}, \quad (10)$$

these are Banach spaces. The spaces $H^k(I) \equiv W^{k,2}(I)$ are Hilbert spaces when equipped with the inner product

$$(f, g)_{H^k} = \sum_{j=0}^k (D^j f, D^j g)_{L^2}. \quad (11)$$

FUNCTIONAL ANALYSIS

Introduction

Systems that are extended in space are usually modeled by partial differential equations (PDEs). The solution of such an equation will be a function of both space and time, for example, $u(x, t)$, and so the state of the system is specified by the function $f(\cdot) = u(\cdot, t)$. Since the resolution of such a function as a Fourier series

$$f(x) = \sum_{k \in \mathbb{Z}} c_k e^{ikx}, \quad c_{-k} = \overline{c_k},$$

requires an infinite number of coefficients, the appropriate phase space for a PDE is generally infinite-dimensional. For example, the stability of a solution (be it stationary, periodic, or more general still) will depend on the eigenvalues of some linear operator that acts on this infinite-dimensional phase space.

Broadly speaking, functional analysis can be viewed as the study of infinite-dimensional spaces and the properties of maps (often linear) defined on them. Functional analysis is required for any rigorous treatment of PDEs (e.g., Evans, 1998, or Robinson, 2001) and many problems in the theory of ordinary differential equations.

In this entry we discuss two topics, both central to the subject. First, we give a very brief outline of spectral theory, which generalizes ideas familiar from linear algebra; and then we discuss the notion of “weak convergence” that goes some way to circumventing the problems arising from a fundamental difference between finite- and infinite-dimensional spaces.

For the sake of simplicity, we will discuss these two topics only in the context of a Hilbert space rather than for a general Banach space (See **Function spaces**). We denote this Hilbert space by H , its norm by $\|\cdot\|$, and its inner product by $(\cdot, \cdot)$. Note that $\mathbb{R}^n$ is a finite-dimensional Hilbert space. For more details and a more general treatment, see the suggestions for further reading.

Spectral Theory

Initially motivated by Sturm–Liouville boundary value problems and the related theory of integral equations, spectral theory has become an important part of functional analysis. The theory generalizes ideas from finite-dimensional linear algebra to linear operators on infinite-dimensional spaces.

A map $A : H \rightarrow H$ is linear if

$$A(x + \lambda y) = Ax + \lambda Ay \quad \text{for every } x, y \in H, \\ \lambda \in \mathbb{R},$$

and is *bounded* if, for some $M > 0$,

$$\|Ax\| \leq M\|x\| \quad \text{for every } x \in H. \quad (1)$$

[If $H = \mathbb{R}^n$, then any linear map is bounded, but this is not true when H is infinite-dimensional.]

When $H = \mathbb{R}^n$, the eigenvalues of a matrix A are all those complex numbers λ for which $A - \lambda I$ is not invertible (so that $Ax = \lambda x$ for some nonzero x). When A is a linear operator on an infinite-dimensional space, the *spectrum* of A consists of all the values of λ for which $R_\lambda(A) = (A - \lambda I)^{-1}$ lacks one or more of the following “nice” properties:

- (i) $R_\lambda(A)$ exists,
- (ii) $R_\lambda(A)$ is bounded, and
- (iii) $R_\lambda(A)$ can be defined on a dense subset of H (another “nice” property whose exact meaning is unimportant here).

In general, this spectrum can be divided into three distinct pieces:

- the point spectrum $\sigma_p(A)$ (eigenvalues): (i) does not hold, so that there is a nonzero $x \in H$ (the “eigenfunction”) with $Ax = \lambda x$;
- the continuous spectrum $\sigma_c(A)$: (i) and (iii) hold, but not (ii), and
- the residual spectrum $\sigma_r(A)$: (i) holds but (iii) does not.

If $H = \mathbb{R}^n$, then whenever (i) holds so do (ii) and (iii), and the spectrum consists only of the eigenvalues of A .

When $H = \mathbb{R}^n$ and A is a real symmetric matrix, results from linear algebra guarantee that (a) all its eigenvalues are real, (b) the eigenvectors corresponding to distinct eigenvalues are orthogonal, and (c) the eigenvectors form a basis for $\mathbb{R}^n$. To obtain a similar result when H is infinite-dimensional we have to impose certain restrictions on A . The original applications to boundary value problems and integral equations motivated the following two definitions that are useful here: an operator $A : H \rightarrow H$ is *compact* if the image $\{Ax_n\}_{n=1}^\infty$ of any bounded sequence $\{x_n\}_{n=1}^\infty$ has a convergent subsequence [if $H = \mathbb{R}^n$, then any linear map is compact, cf. below]; and a bounded map from a Hilbert space H into itself is *self-adjoint* if

$$(Ax, y) = (x, Ay) \quad \text{for every } x, y \in H$$

[when $H = \mathbb{R}^n$, this means that A is a real symmetric matrix].

If A is a compact, self-adjoint operator that is also invertible, then it behaves much like a real symmetric matrix: (a) all of its eigenvalues are real; (a') the residual spectrum is empty and there are at most a countable number of eigenvalues, which are bounded and can only have zero as an accumulation point; (b) eigenfunctions corresponding to distinct eigenvalues are orthogonal; and (c) the eigenfunctions form a basis for H . This is the celebrated Hilbert–Schmidt theorem, the rigorous result that justifies the approach of Sturm–Liouville theory, that is, using eigenfunctions as a basis in which to expand solutions as a “generalized Fourier series” (see Kreyszig, 1978; Renardy & Rogers, 1992, for example).

Weak Convergence

A space is finite-dimensional if and only if its unit ball is compact. Put another way, any bounded sequence in a finite-dimensional space has a convergent subsequence (in $\mathbb{R}$ this is the Bolzano–Weierstrass theorem); this result is extremely useful, but it is not true in an infinite-dimensional space.

However, it is possible to define a weaker notion of convergence (“weak convergence”) and so recover a form of this compactness property in certain infinite-dimensional spaces. To motivate the definition we make two observations. First, if x and y are two distinct elements of a Hilbert space H , then, it is possible to find a $z \in H$ such that

$$(z, x) \neq (z, y),$$

“inner products can distinguish elements of H .” Second, it is also possible to show that if $(z, x) = (z, y)$ for every $z \in H$, then we must have $x = y$: “inner products can determine elements of H .”

Because of these two results, it is reasonable to define a notion of convergence based on inner products. In a Hilbert space, a sequence x_n converges weakly to x , written $x_n \rightharpoonup x$, if

$$(x_n, z) \rightarrow (x, z) \quad \text{for every element } z \in H.$$

Although a bounded sequence in an infinite-dimensional Hilbert space need not have a convergent subsequence, it will have a subsequence that converges weakly. Such convergence is often sufficient for applications; in particular, it is fundamental to many results in the theory of existence and uniqueness for solutions of PDEs.

[The Riesz Representation theorem guarantees that for any bounded linear map $\rho : H \rightarrow \mathbb{R}$, there is a $z \in H$ such that $\rho(x) = (z, x)$ for all $x \in H$. In a general Banach space B , the “inner product with” z used above is replaced by “any bounded linear map from B into $\mathbb{R}$ ”. These maps are known as “linear functionals,” and

gave rise to the name of the subject to which they are central.]

GALAXIES

Galaxies are dense agglomerations of matter in the Universe. They consist of gas, dust, and stars as a major fraction. In addition, for kinematical reasons a hypothetical “dark matter” component is required. Their formation dates back to the early Universe, almost 14 billion years ago. Although some galaxies were already listed as nebulous objects in Charles Messier’s catalogue of nebulae and star clusters from 1784, their discovery as detached “island universes” only dates from 1924, when Edwin Hubble resolved the outer parts of Messier Object 31 (M31, the Andromeda Nebula) into stars and measured their distances.

Within 2.2 million light years ($1 \text{ ly} = 9.46 \times 10^{12} \text{ km}$), M31 is the closest massive galaxy and is similar to our Milky Way galaxy, both belonging to a galaxy type that is characterized by a rotating disk of stars and gas showing spiral patterns. In addition, such spiral galaxies possess a central spheroid of old stars called a bulge and an extended spheroidal halo of old single stars and bound star clusters, called globular clusters.

All spiral galaxy labels today begin with the prefix “S”. For decreasing bulge-to-disk ratios, Hubble classified the sequence of spirals from Sa to Sc, some of which also show an innermost bar structure where the spiral arms emerge at the ends. Hubble distinguished these as SBs as distinct from normal Ss.

Another morphological galaxy type exists with an elliptical shape, almost no particular substructure, relatively old stars, and depleted in gas: ellipticals. According to their minor-to-major axes ratio b/a , Hubble denoted them by E10($1 - b/a$) reaching from E0 (circular) to E7 ($b/a = 0.3$) at most.

Lenticular galaxies (S0s) form the link between spirals and ellipticals in Hubble’s famous “tuning-fork diagram” (see Figure 1). Hubble galaxies have masses between several 10^{10} to 10^{12} solar masses ($m_s = 1.9891 \times 10^{30} \text{ kg}$) and diameters of 100,000 light years and more. More refined classification schemes are possible such as those by de Vaucouleurs (1959) and Sandage (1961). Today an extension exists to Sds, and even further to irregularly shaped galaxies (Is) with lower mass and brightness and no central bulge.

Figure 1. Hubble’s “tuning-fork diagram” of galaxies. With courtesy from STScI.

Internal and Dynamical Structure of Galaxies

Ellipticals

According to the stellar mass distribution, any galaxy becomes dimmer with distance R from the geometrical center. The radial dependence however, differs between morphological types and their components. Ellipticals follow in all directions the empirical de Vaucouleurs law with brightness falling off with $\exp(-R^{1/4})$. Although it seems plausible that rotation causes ellipticity, since the 1970s, it has been known that in most ellipticals their regular rotation velocity is smaller than the irregular proper motion of stars with speeds of 200–250 km/s. They are therefore denoted as “hot stellar systems.” The elliptical shape is thus formed by the anisotropic velocity dispersion of stars. Moreover, triaxiality of the figure axes, as for a flattened cigar, can be derived for some elliptical galaxies if the elliptical contours of equal brightness are somehow twisted. Most elliptical galaxies can be divided additionally into boxy- or disk-shaped contours considering the fourth-order cosine in a trigonometric expansion.

Spirals

Spiral galaxies are the most complex systems. While their bulges’ brightness profiles resemble ellipticals,

they are rotationally supported. Although the halos are not dense enough to show a continuous stellar distribution, one can take, for example, globular clusters as representative and find a power law for the density of $R^{-2} \dots R^{-3.5}$. While in the halo, the large irregular velocities of stars (determined in our Milky Way) and globular clusters, their age, and the lack of significant amounts of gas are similar to those of ellipticals (without knowing the halo's ellipticity), disks consist of 10–20% gas and of stars, both rotating with velocities of 200–250 km/s. Because the velocity dispersion of stars is much less, in the range of only 10–60 km/s, disks are therefore “cold systems” and rotationally flattened. Their radial face-on brightness drops with $\exp(-R/\alpha)$ where α is the so-called scale length of around 10,000 light years.

Although spiral arms are exceptionally trailing, they are not the result of structures wound by differential rotation because their pitch angles, that is, the angle between an arm and a circle, should be much smaller than observed. Because the arm structure is pronounced in the visual by the brightness of young stars that form out of cold gas condensed within the arms, among different possible processes of arm formation, density waves are the most favored.

Since the characteristic velocities v , for example, the rotation of spiral disks and velocity dispersion in elliptical galaxies, are almost constant with R , although the visible mass decreases, this invokes the existence of dark matter. Because in equilibrium the centrifugal force $F_c = mv^2/R$ acting on the mass element m is balanced by the gravitational force of a mass M_R included within R , $F_g \propto mMR/R^2$, for observed $v = \text{const}$. M_R has to increase with R . This means that the dark matter contribution dominates in the outermost regime. In contrast, less bright ellipticals have been found recently where a decline of velocities at large radii is measured, so the dark matter content remains controversial.

Formation and Evolution of Galaxies

Galaxies assemble into larger units by means of gravitation, thus forming galaxy groups like our Local Group and galaxy clusters with numerous members, as for example, the Virgo Cluster at a distance of 50 million light years. In the center of the clusters, ellipticals dominate while spirals permeate the whole cluster. This leads to the suggestion that ellipticals are formed by merging events in the densest cluster regions and in the early universe.

While the Hubble-type galaxies are massive, dwarf galaxies with less mass exist. In our vicinity the large and small magellanic clouds (LMC, SMC) as satellites of the Milky Way represent a dwarf irregular type, consisting of gas and stars as spirals but with less regular structures. With masses of $5 \times 10^9 m_\odot$, the LMC lies at the upper-mass range of dwarf galaxies, while

other Milky Way galaxy satellites, dwarf spheroidals, form the low-mass end of the dwarf ellipticals. With 10^6 – $10^7 m_\odot$, their brightness is so low that observations are still incomplete. Dwarf ellipticals are the most frequent galaxy type in the present Universe resembling Hubble's Es.

The class of dwarf galaxies is of substantial importance for our understanding of galaxy formation and the evolution of the Universe, because they serve as the building blocks of massive galaxies in the cosmological picture of hierarchical clustering. Although their accretion by mature galaxies by means of tidal friction is observable, their destruction rate during the course of the universe is yet unclear because it is also possible that the dwarf galaxy types are replenished by other processes such as tidal tails of merging galaxies.

GAME OF LIFE

The rules underlying Life are simple, according to computer scientists. Biologists are inclined to be skeptical, but they do agree that the cellular automaton known as the Game of Life provides fascinating insights into the phenomena of self-organization and emergence in systems of interacting agents.

Biological life has been around for at least 3.8 billion years, but the Game of Life was invented by mathematician John Conway in 1970 and publicized by Martin Gardner in his “Mathematical Games” column in *Scientific American*. It is probably the best-known example of the class of algorithms known as cellular automata (CA). A CA is a one- or two-dimensional array of cells, each of which can exist in a number of states. Time in a CA is discrete; at each time step, every cell updates itself on the basis of its current state and those of its neighbors. Cellular automata can exhibit surprisingly complex global temporal

Figure 1. Some commonly seen patterns in the Game of Life.

dynamics, arising from extremely simple rules applied on a local scale.

The standard Game of Life uses a two-dimensional grid. Cells can be either on (alive) or off (dead). The neighborhood of a cell is the eight cells surrounding it. The rules of Life are, indeed, simple; if a live cell has two or three live neighbors, it stays alive. A dead cell with exactly three live neighbors comes alive (is born). In all other cases the cell dies, either of overcrowding (with more than three live neighbors) or loneliness (with fewer than two). At each time step, all cells update their states simultaneously. That's all there is to Life! No wonder the biologists are dubious. But from this simple foundation, complex, consistent patterns of activity emerge. If the grid is seeded at random with live cells, the first few time steps are a turmoil of apparently random activity. However, identifiable patterns of live cells quickly emerge. Interesting patterns exhibit periodic behavior, cycling between a number of different states in a deterministic manner. Many patterns settle into a limit cycle of length one—a stable point attractor, or “still life” in the Life terminology. Others, known to Life practitioners as “oscillators,” have longer limit cycles.

So consistent are these patterns that hundreds have been identified, named, and studied by Life enthusiasts all over the world (see e.g., Figure 1). There are several catalogues of Life patterns available on the Web; a particularly nice site is <http://hensel.lifepatterns.net/>.

Although most initial configurations eventually settle to a stable state or cyclic set of states, this is not

always the case. Life aficionados have identified initial states that generate new states indefinitely.

So is Life more than just a generator of interesting patterns? The answer, of course, is “yes.” Cellular automata in general, and Life in particular, have interesting theoretical properties. Stephen Wolfram identified four broad classes of dynamic behavior common to one-dimensional (Wolfram, 1984) and two-dimensional (Wolfram, 1985) CAs.

Class 1: Evolution leads to a homogeneous state (analogous to a point attractor in a nonlinear dynamic system),

Class 2: Evolution leads to a set of separated simple stable or periodic structures (analogous to limit cycles),

Class 3: Evolution leads to a chaotic pattern (analogous to the chaotic attractors found in continual dynamic systems),

Class 4: Evolution leads to complex localized structures, sometimes long-lived.

Although the universal applicability and hence usefulness of Wolfram’s classification system has been questioned (e.g., Eppstein, 2000), it is still widely accepted. The Game of Life falls, serendipitously, into class 4, the class for which Wolfram hypothesizes that “class-4 cellular automata are generically capable of universal computation, so that they can implement arbitrary information-processing procedures” (Wolfram, 1985). It has, in fact, been proven that Life is a universal cellular automaton—one which can emulate a Turing machine, capable of performing universal

Figure 2. State transition graph for a cellular automaton. States are arbitrarily numbered. The state space contains four basins of attraction, three of which contain a point attractor, while the fourth leads to a limit cycle of length three (states 81, 82 and 83).

computation. The universality of Life was proved in the early 1980s (Berlekamp et al., 1982), and a Turing machine that can be extended to a universal Turing machine was implemented by Paul Rendell in 2000 (Adamatzky, 2002).

An overview of the temporal dynamics of a two-dimensional CA such as the Game of Life can be provided by a state transition graph, in which each possible pattern of on and off cells in the CA makes up a unique state. If the number of cells in the lattice is s and the number of cell states is k , then there are k^s possible states for that CA. Each state forms a node in the graph. Since the rules are deterministic, each state will map to a single new state in the next timestep, and the transition between the two states is represented by a directed link (an arc) between the two nodes. A state transition graph depicts the course of evolution of the CA from any given starting point (Figure 2).

Inspection of a state transition diagram leads to the conclusion that evolution in a CA is not deterministically reversible; some states have two or more antecedent states. Some states, in contrast, have no preceding states. The latter are known as Garden of Eden states. The existence of Garden of Eden states in the Game of Life was predicted by CA theory, but actually identifying such a state is a nontrivial task. Several Garden of Eden states have been identified by trial and error, but the search for a reliable algorithm for their identification continues.

The rules of Life are simple, but from them arise complex, emergent behaviors—coherent forms arising at different levels of organization and interacting to produce new forms and patterns. This complexity arising from underlying simplicity makes the Game of Life an ideal toy world for the study of many of the fascinating phenomena of complex systems.

GAME THEORY

Humans play games. From the formalized warfare of chess to the Machiavellian machinations of politics to the subtleties of sexual pursuit, interactions between individuals with desires and priorities that are often conflicting and contradictory lies at the heart of human society. The formal study of games, however, is a relatively recent phenomenon and has moved rapidly from its beginnings as a mathematical tool to aid gamblers to its current status as an essential paradigm in fields as diverse as economics and evolutionary biology.

Today, *game theory* can be defined as “the analysis of rational behavior under circumstances of strategic interdependence, when an individual’s best strategy depends upon what his opponents are likely to do” (Varoufakis, 2001). Individuals may be people, corporations, nations, animals, species, or any other entity that can be said to exhibit strategic behavior.

Formal game theory began in 1713, when Pierre-Rémond de Montmort first proposed the concept of a minimax solution to a card game called *Le Her*. A minimax solution to a two-player game is one in which an individual chooses his strategy so as to minimize the maximum loss or risk that he/she will incur. It was James Waldegrave, the originator of *Le Her*, who actually produced a minimax solution to the game.

Other concepts of fundamental importance to modern game theory also emerged in the 18th century, a result of work by Daniel Bernoulli in his 1738 analysis of the St. Petersburg paradox (Dimand & Dimand, 1992). These concepts included utility (a measure of the desirability to the player of each possible outcome of the game), the maximization of expected utility, diminishing marginal utility (the decrease in the amount of benefit derived from consuming each additional unit of a product or service), and risk aversion as a parameter of a utility function.

The work on minimax game solutions remained an isolated curiosity until the 1920s, when Émile Borel published a series of short papers on strategic games in the *Proceedings of the French Academy of Sciences* between 1921 and 1927. In these papers, he defined the normal form of a game: a matrix representation of the game in which each player tries to work out the best strategy independent of the sequence of moves. Borel later claimed to have proven the minimax theorem, but this does not appear to be the case. In fact, he may not even have stated the theorem.

The first formal proof of the minimax theorem for two-person games with any finite number of pure strategies was given by John von Neumann in a paper presented to the Gottingen Mathematical Society on December 7, 1926 (Dimand & Dimand, 1992). He proved that in a zero-sum game (one in which one player’s gain is the other’s loss), there exists a unique set of mixed strategies, one per player, which equalizes

the payoffs that each player can gain regardless of the strategy adopted by the other player.

At about the same time, the Princeton economist Oskar Morgenstern was pondering mixed strategy game theoretic issues, as exemplified by that master of bluff, Sherlock Holmes, and the strategies he should adopt to avoid his arch enemy, Professor Moriarty. In 1944, von Neumann and Morgenstern collaborated to produce *The Theory of Games and Economic Behavior*, the seminal publication in this area. In 1947, they revised the book to include expected utility theory, under which games are expressed in terms of the players’ perceptions of the inherent desirability and likelihood of their outcomes, and players never expect other players to hold mistaken beliefs—the assumption of complete rationality, which has been fundamental to much ensuing work. Economists were initially reluctant to accept game theory, but since the publication of von Neumann and Morgenstern’s book, the theory has undergone extensive development, and has been applied to an enormous variety of problems in economics, to the point where Leonard (1992) could assert that “game theory plays a central role in economic theory.”

Minimax theory assumes that each player has perfect knowledge about the game and that the game is zero-sum. In such a case, the best strategy for each player is independent of the strategy adopted by the other player. In most real-world situations, this is not the case; more often, the best strategy for one player depends on what the other players choose to do. The extension of minimax theory to *n*-player, noncooperative games was achieved by the Princeton mathematician John Nash in a paper published in 1950. In this paper, he defined the Nash equilibrium. A Nash equilibrium is a set of strategies such that no player could improve his/her payoff, given the strategies of all other players in the game, by changing his/her strategy. Nash proved that all noncooperative games have a Nash equilibrium and, thereby, established an analytical structure within which all situations of conflict and cooperation could be studied. For this work, he received the 1994 Nobel Prize for Economics, together with John Harsanyi and Reinhard Selten.

Game theory was also applied with considerable success to other fields of research, perhaps most notably to evolutionary biology. The concepts of game theory transfer readily to evolutionary biology—the values of different outcomes, which in economic theory are measured as utility, are readily interpreted in terms of Darwinian fitness. Moreover, the somewhat sweeping assumption of complete rationality in the behavior of the agents is replaced by the concept of evolutionary stability.

Game-theoretic concepts were first explicitly applied to the study of evolution by Lewontin (1961), who saw the agents in the game as a species on the one hand,

against nature on the other. The utility of this approach was quickly recognized, and the focus shifted to modeling interactions between individuals. In this context, the concept of the Nash equilibrium was rediscovered independently by John Maynard Smith and G.R. Price in 1973 as the Evolutionarily Stable Strategy (ESS—"a strategy such that, if all the members of a population adopt it, no other strategy can invade" (Maynard Smith, 1982, p. 204). An ESS represents the solution to a game.

In the last three decades, game theory has been used to provide a framework for the analysis of a wide range of biological phenomena, including the evolution of sex ratios, parental investment in offspring, patterns of animal dispersal, competition for resources (see, e.g., Maynard Smith, 1982) and the evolution of cooperation (Axelrod, 1984). In biology, as in economics, game theory has become an essential tool for the theorist, providing a structured framework for the analysis of a wide range of phenomena.

GEL'FAND-LEVITAN THEORY

In inverse problems, sometimes also called backward problems, one is given the solution and required to find the underlying equation. Inverse spectral problems deal with the recovery of unknown coefficients of a differential operator from the knowledge of its spectral data. Their importance stems from the fact that coefficients in a differential equation usually model the physical structure or composition of a certain material. Nondestructive testing, geophysical prospecting, radar, and medical imaging are just some of the important applications of inverse problems. By analyzing reflected waves, radar can locate, track, and sometimes identify a target. In geophysical prospecting, the travel time of reflected underground acoustic waves can reveal deposits of petroleum and natural gas. The field of medical imaging has witnessed the development of many non-invasive and safe procedures using the above ideas. For example, ultrasonography using the three-dimensional Doppler effect can help visualize the fetal vascular system for prenatal diagnosis. High-resolution ultrasound cardiovascular imaging not only reconstructs a real-time picture of the heart but also measures the rate of blood flow, thus giving early warnings for clogged arteries, heart attacks, and strokes.

A simple rule of the thumb is that data used should be equivalent to the information to be reconstructed. For example, if we are looking for a square integrable function, the data should be equivalent to its sequence of Fourier coefficients, while an analytic function is equivalent to its Taylor coefficients. Can we recover a matrix of size $n \times n$ from its n eigenvalues? Although in general to define a matrix we would need n^2 entries, possible exceptions would be matrices that are fully determined by their first rows—symmetric Toeplitz or Hankel matrices, for example. In all kinds of inverse problems, one faces two major issues: uniqueness of the solution and the algorithm for its reconstruction. One of the best understood inverse problems, which deals with the Schrödinger operator, was solved by Gel'fand and Levitan in 1951 (see Gel'fand & Levitan, 1955).

The One-dimensional Schrödinger Equation

Consider the one-dimensional Schrödinger operator

$$\begin{cases} L(y) = -y''(x, \lambda) + q(x)y(x, \lambda) = \lambda y(x, \lambda), \\ x \in [0, \infty), \\ y'(0, \lambda) - hy(0, \lambda) = 0, \end{cases} \quad (1)$$

where q is a real continuous function and h is a real constant. The continuity of q ensures the existence of a

unique solution of the initial value problem at $x = 0$ for every $\lambda \in \mathbb{C}$. The boundary value problem (1) is regular at $x = 0$ and singular at $x = \infty$. The operator L , which acts in the Hilbert space of square integrable functions on the positive half line, is self-adjoint so its eigenvalues are real. We usually normalize solutions of (1) by the condition $y(0, \lambda) = 1$, which leads to $y'(0, \lambda) = h$. To determine the spectrum of L (the set of values λ such that the inverse operator of $L - \lambda I_d$ either does not exist or is unbounded), we need to examine the behavior of the solutions $y(x, \lambda)$ as $x \rightarrow \infty$. If the solution decays fast enough and is square integrable, that is, has a finite energy $\alpha_n = \int_0^\infty |y(x, \lambda_n)|^2 dx < \infty$, then λ_n is an eigenvalue and belongs to the discrete part of the spectrum. For other solutions that could be approximated by continuous functions or do not grow faster than a polynomial in x , λ belongs to the continuous spectrum; otherwise λ is not in the spectrum. A more precise result using the theory of distributions (Gel'fand & Shilov, 1967) shows that λ is in the spectrum if and only if the solution $y(x, \lambda)$ is the derivative of a function that cannot grow faster than $x^{3/2+\varepsilon}$ as $x \rightarrow \infty$. This characterization threw a new light on the mysterious behavior of the continuous spectrum.

For example, when $q = h = 0$, the spectrum of L is continuous on $[0, \infty]$. Indeed its "eigenfunctions" are $\cos(x\sqrt{\lambda})$ which are not square integrable and so there are no eigenvalues, while for $\lambda > 0$ the solutions $\cos(x\sqrt{\lambda})$ are bounded and so grow less than $x^{3/2+\varepsilon}$ as $x \rightarrow \infty$, which means that $\lambda > 0$ is in the continuous spectrum. On the other hand, when $\lambda < 0$, the solutions $\cos(x\sqrt{\lambda}) = \cosh(x\sqrt{-\lambda})$ have an exponential growth, and so $\lambda < 0$ cannot be not in the spectrum.

Once the operator L is known to be self-adjoint, the solution $y(x, \lambda)$ forms the kernel of a transform, which is similar to the Fourier cosine transform,

$$F(\lambda) = \int_0^\infty f(x)y(x, \lambda) dx,$$

and its inverse transform is defined explicitly by

$$f(x) = \int_\sigma F(\lambda)\overline{y(x, \lambda)} d\rho(\lambda).$$

The function ρ , which is called the spectral function, is nondecreasing, is right-continuous, has jumps at the eigenvalues $\rho(\lambda_n) - \rho(\lambda_n - 0) = 1/\alpha_n$, and is continuous and increasing only on the continuous part of the spectrum. For example, when $q = h = 0$, the spectral function is simply

$$\rho_0(\lambda) = \begin{cases} (2/\pi)\sqrt{\lambda} & \text{if } \lambda \geq 0, \\ 0 & \text{if } \lambda < 0. \end{cases}$$

Obviously when $q \neq 0$, the new spectral function ρ would record all new spectral changes, which leads to

the inverse spectral problem: by comparing ρ to ρ_0 can we recover the perturbation q ?

Gel'fand-Levitant Theory

If we are given a spectral function ρ , can we find its associated Sturm-Liouville differential operator given in (1)? This is in essence the Gel'fand-Levitant theory, which produced an elegant algorithm for the recovery of the potential q and the boundary condition at $x = 0$.

As explained earlier, the spectrum depends on the growth of solutions and a key point is their representations by the Fourier transform,

$$y(x, \lambda) = \cos(x\sqrt{\lambda}) + \int_0^x K(x, t) \cos(t\sqrt{\lambda}) dt. \quad (2)$$

The kernel $K(x, t)$ is continuous and contains all information about q , namely, that

$$\frac{d}{dx} K(x, x) = \frac{1}{2} q(x) \text{ and } K(0, 0) = h. \quad (3)$$

Thus, it is a matter of finding $K(x, t)$ in order to recover q . To do so, we first form the function

$$F(x, t) = \int_{-\infty}^\infty \frac{\sin(x\sqrt{\lambda})}{\sqrt{\lambda}} \frac{\sin(t\sqrt{\lambda})}{\sqrt{\lambda}} d\sigma(\lambda), \quad (4)$$

where the given spectral function ρ is used in

$$\sigma(\lambda) = \begin{cases} \rho(\lambda) - \frac{2}{\pi}\sqrt{\lambda} & \text{if } \lambda \geq 0, \\ \rho(\lambda) & \text{if } \lambda < 0 \end{cases} \quad (5)$$

and set

$$f(x, t) = \frac{\partial^2 F(x, t)}{\partial x \partial t}.$$

The crux of the theory is that $f(x, t)$ and $K(x, t)$ satisfy a linear integral equation, for each fixed x

$$K(x, t) + \int_0^x K(x, s) f(s, t) ds = -f(x, t) \quad \text{for } 0 \leq t \leq x. \quad (6)$$

Thus given the spectral function ρ , we can form $F(x, t)$ by (4), yielding the kernel $f(x, t)$ and then for each fixed x solve the Fredholm integral equation (6) for $K(x, t)$. As for matrices, a Fredholm integral equation has a solution if the null space contains only the trivial solution. Once the existence of a solution K is guaranteed, its smoothness is examined. It is shown that $f(x, t)$ and $K(x, t)$ have the same degree of smoothness which implies the smoothness of q by (3). The original

Gel'fand-Levitán result in (1951) is based on the linear equation (6) and can be summarized as follows:

Theorem 1 (Gel'fand and Levitan Theory). *If a non-decreasing function $\rho(\lambda)$ satisfies*

(A) *for arbitrary real x the integral*

$$\int_{-\infty}^0 \exp(x\sqrt{|\lambda|}) d\rho(\lambda) \text{ exists,}$$

(B) *the integral*

$$a(x) = \int_1^{\infty} \frac{\cos(x\sqrt{\lambda})}{\lambda} d\sigma(\lambda)$$

exists for all $0 \leq x < \infty$, while $a(x)$ has continuous derivatives up to the fourth order for all $0 \leq x < \infty$ and if the set of points of increase of ρ has at least one finite accumulation point, then there exists just one differential operator of the second order defined by (1) which has $\rho(\lambda)$ as its spectral function. The function $q(x)$ and the number h are defined by (3), where $K(x, t)$ is a solution of (6).

However, the original theory had a gap between the necessary and sufficient conditions. Ten years later, Levitan and Gasymov proved a stricter version, which we state as the Gel'fand-Levitán-Gasymov theory found in Gasymov & Levitan (1964) that contains necessary and sufficient conditions.

Theorem 2 (Gel'fand-Levitán-Gasymov). *The monotonically increasing function ρ is the spectral function of a Sturm-Liouville of type (1) with a function q having m integrable derivatives and a number h if and only if the following conditions are satisfied:*

(A) *If $E(\lambda) = \int_0^{\infty} f(x) \cos(x\sqrt{\lambda}) dx$, where $f \in L^2(0, \infty)$ and of compact support, then*

$$\int |E(\lambda)|^2 d\rho(\lambda) = 0 \implies f = 0 \text{ almost everywhere.}$$

(B) *The limit $\Phi(x) = \lim_{N \rightarrow \infty} \int_{-\infty}^N \cos(x\sqrt{\lambda}) d\sigma(\lambda)$, where $\sigma(\lambda)$ is defined by (5), exists boundedly in every finite range of values of x and Φ has $m+1$ locally integrable derivatives with $\Phi(0) = -h$.*

There are also interesting results for the regular case that is defined by

$$\begin{cases} L(y) = -y''(x, \lambda) + q(x)y(x, \lambda) = \lambda y(x, \lambda), \\ 0 \leq x \leq \pi, \\ y'(0, \lambda) - hy(0, \lambda) = 0, \\ y'(\pi, \lambda) - Hy(\pi, \lambda) = 0, \end{cases} \quad (7)$$

where q is continuous and $q, h, H \in \mathbb{R}$. Let the norming constants be defined by $\alpha_n = \int_0^{\pi} |y(x, \lambda_n)|^2 dx$.

Note that since q is continuous, its knowledge is equivalent to its sequence of Fourier coefficients. Thus, the data ought to be at least an infinite sequence of numbers in order to recover the potential q .

Theorem 3. *If all the $\alpha_n > 0$,*

$$\sqrt{\lambda_n} = n + \frac{a_0}{n} + \frac{a_1}{n^3} + O\left(\frac{1}{n^4}\right)$$

and

$$\alpha_n = \frac{\pi}{2} + \frac{b_0}{n^2} + O\left(\frac{1}{n^3}\right),$$

where a_0, a_1 , and b_0 are constants, then there exists an absolutely continuous function $q(x)$ corresponding to the given λ_n and α_n .

Theorem 4. *The numbers $\{\lambda_n\}_{n=0}^{\infty}$ and $\{\alpha_n\}_{n=0}^{\infty}$ are the spectral data of some boundary value problem (7) with q'' being square integrable if and only if the following asymptotic estimates hold:*

$$\sqrt{\lambda_n} = n + \frac{a_0}{n} + \frac{a_1}{n^3} + \frac{\gamma_n}{n^3}$$

and

$$\alpha_n = \frac{\pi}{2} + \frac{b_0}{n^2} + \frac{\tau_n}{n^3},$$

where $\lambda_n \neq \lambda_m$ and $\alpha_n > 0$ and the series $\sum_{n=1}^{\infty} \gamma_n^2$ and $\sum_{n=1}^{\infty} \tau_n^2$ are convergent.

The problem of generalizing the theory to higher dimensional operators remains open and depends heavily on the idea of transformation operators that map generalized functions. In Boumenir (1991), it is also proved that the Gel'fand-Levitán theory is based on the factorization of operators whose symbol is given by the spectral functions.

Discrete Case

Consider now a discrete version of the Sturm-Liouville problem

$$Bv = \lambda Av, \quad (8)$$

where B is a Jacobi matrix and A is a diagonal matrix with positive entries (positive definite). Expressing (8) in a vectorial form, we end up with recurrence relation defined by

$$\begin{cases} c_n y_{n+1} = (a_n \lambda + b_n) y_n - c_{n-1} y_{n-1}, \\ n = 0, \dots, m-1, \\ y_{-1} = 0, \text{ and } y_m + h y_{m-1} = 0, \end{cases} \quad (9)$$

where $b_n \in \mathbb{R}$, $a_n > 0$, and $c_n > 0$. We look for a nontrivial finite sequence $y_{-1}, \dots, y_m$ which satisfies (9). To this end, we normalize the solution vectors by $y_0 = 1/c_{-1}$, then knowing the first terms y_{-1} and

y_0 allows us to compute recursively the remaining entries that are now functions of λ . It is easy to see that eigenvalues λ_r are nothing other than the zeros of the last condition $y_m(\lambda) + h y_{m-1}(\lambda) = 0$. For a given eigenvector, define its squared norm by $\alpha_r = \sum_{k=0}^{m-1} a_k |\lambda_k(\lambda_r)|^2$. The following theorem is found in Atkinson (1964) or in Teschl (2000).

Theorem 5. Assume that we are given $h \in \mathbb{R}$, $\{a_k > 0\}$, eigenvalues $\{\lambda_r\}_{0 \leq r \leq m-1}$, norming constants $\{\rho_r\}_{0 \leq r \leq m-1}$, then there exists $\{c_k\}_{-1 \leq k \leq m-1}$ which are positive and constants $\{b_k\}_{0 \leq k \leq m-1}$ such that the boundary value problem has the set $\{\lambda_r\}_{0 \leq r \leq m-1}$ as its eigenvalues.

GENERAL CIRCULATION MODELS OF THE ATMOSPHERE

Atmospheric general circulation models (AGCMs) simulate the dynamical, physical, and chemical processes of planetary atmospheres. For the Earth's atmosphere (See **Atmospheric and ocean sciences**), they are based on the thermo-hydrodynamic equations, which consist of the conservation of momentum, mass, and energy with the ideal gas law in coordinates suitable for the rotating planet.

In the presently used form, they were first derived by Vilhelm Bjerknes in 1904; subsequently, Lewis Fry Richardson (1922) proposed numerical weather prediction (NWP) as a practical application which, in 1950, was successfully performed by Jule Charney, R. Fjørtoft, and John von Neumann on an electronic computer based on a simplified set of these equa-

tions. While numerical weather prediction models utilize the atmospheric short-term memory for forecasting, AGCMs developed since the 1960s extend applications to longer time scales simulating seasonal and climate variability (for a personal recollection, see Smagorinsky, 1983).

Since then, numerical weather prediction and atmospheric general circulation modeling have enjoyed continuous advances, which are attributed to the following gains and improvements: (1) observational data accuracy, analysis, and assimilation; (2) insight into dynamical and physical processes, numerical algorithms, and computer power; and (3) the use of model hierarchies to study individual atmospheric phenomena. With simulations of the Earth system and that of other planets envisaged, a broad field of science has been established, which is of vital importance socio-economically, agriculturally, politically, and strategically.

Observations

Since the foundation of the World Meteorological Organization (WMO) and international treaties to monitor and record meteorological and oceanographical data, the collection of global data through local weather and oceanic stations has been systematically organized and has become a truly globalized system through the deployment of satellites and introduction of remote sensing facilities. The availability of extensive global data has enabled the extension of NWP models to complex global GCMs, thus facilitating simulations on larger time scales (months and years instead of hours and days) and validation of NWPs in return. Furthermore, it has become possible to study climate history and make estimates of future climates, which is particularly important due to likely anthropogenic impacts.

General Circulation Models

Atmospheric general circulation models have two basic components. First, the dynamical core consists of the primitive equations (the conservation equations with vertical momentum equation approximated by hydrostatic equilibrium, that is, balancing the vertical pressure gradient and the apparent gravitational forces) under adiabatic conditions. Second, physical processes contribute to the diabatic sources and sinks interacting with the dynamical core. They are incorporated as parameterizations, mostly in a modular format: solar and terrestrial radiation, the hydrological cycle (with phase transitions manifested in evaporation and transpiration, cloud, and precipitation processes), the planetary boundary layer communicating between the free atmosphere and the ground (soil with vegetation, snow and ice cover; ocean with sea ice), and atmospheric chemistry. Most of these parameterizations enter the thermodynamic energy equation as heat sources or sinks.

Dynamical core

State-of-the-art atmospheric general circulation models commonly utilize the so-called primitive equation approximation of the Navier–Stokes equations. In addition to the dry dynamics, equations describing the transport of other constituents such as water vapor, cloud liquid water and ice, trace gases, and particles (aerosols) can be an integral part of the dynamical core. To integrate the equations, they are discretized in space and time where finite differences and spectral methods are the most dominant. For more details on the governing equations; *See the entries for Atmospheric and ocean sciences; Fluid dynamics; Navier–Stokes equation.*

- (i) Horizontal discretization: In the horizontal, grid point, or spectral representations of the dependent model variables are used. Different grid structures and finite difference schemes have been designed to reduce the error (Messinger & Arakawa, 1976). An alternative approach is the spectral method. The dependent variables are represented in terms of orthogonal functions where appropriate basis functions are the spherical harmonics. The maximum wave number of the expansion defines the resolution of the model. Since the computation of products is expensive, only linear terms are evaluated in the spectral domain. To compute the nonlinear contributions, the variables are transformed into grid point space every time step, where the respective products are computed and transformed back to spectral space. Necessary derivatives are computed during the transformation. This spectral-transform procedure (Eliassen et al., 1970; Orszag, 1970) makes the spectral approach computationally competitive with finite difference schemes. For low resolutions, the spectral method is, in general, more accurate than the grid point method. However, spectral methods are less suitable for the treatment of scalar fields, which exhibit sharp gradients and, for physical reasons, must maintain a positive-definite value (e.g., water vapor, cloud water, chemical tracers). Therefore, selected fields are often treated separately in the grid point domain using, for example, semi-Lagrangian techniques. Recently, with increasing model resolutions and the need for transporting more species (e.g., for chemical sub-models), grid point models are attracting more attention again, while novel grid structures are introduced, for instance, the spherical icosahedral grid of the German Weather Service model GME (Majewski et al., 2000).
- (ii) Vertical discretization: In general, finite differences and numerical integration techniques are used for the derivatives and integrals in the vertical. The vertical coordinate can be defined in different ways. The isobaric coordinate eliminates

the density from the equations and simplifies the continuity equation compared with a z -coordinate system. However, the intersection of low-level pressure surfaces with the orography enforces time-dependent lower boundary conditions which are difficult to treat numerically. This problem can be avoided if terrain following sigma (σ) coordinates are used, where sigma is defined by the pressure divided by the surface pressure $\sigma = p/p_0$. Unfortunately, the sigma coordinate leads to a formulation of the pressure gradient force which, in the presence of steep orography, is difficult to treat. The advantages of both sigma and pressure coordinates are combined by introducing a hybrid coordinate system with a smoothed transition from σ to p with height.

Physical Processes and Parameterizations

Many processes that are important for large-scale atmospheric flow cannot be explicitly resolved by the model due to its given spatial and temporal resolution. These processes need to be parameterized; that is, their effect on the large-scale circulation needs to be formulated in terms of the resolved grid-scale variables. The most prominent processes in building a parameterization package of an atmospheric general circulation model are long- and short-wave radiation, cumulus convection, large-scale condensation, cloud formation and the vertical transport due to turbulent fluxes in the planetary boundary layer, and the effect of different surface characteristics such as vegetation on the surface fluxes. Additional processes such as the excitation of gravity waves and their impact on the atmospheric momentum budget or the effect of vertical eddy fluxes above the boundary layer are often considered. Because the land surface provides a time-dependent boundary condition that acts on time scales comparable to the atmosphere, great effort has been made to include land surface and soil processes in the atmospheric parameterization package. More recently, the effect of the interaction of various chemical species and their reactions with atmospheric circulation are also being considered. In addition to the direct relation between the resolved atmospheric flow and the effect of the parameterized processes, there are various other interactions among the individual processes that have to be taken into account. For typical comprehensive atmospheric general circulation models, Figure 1 displays the interrelations between the adiabatic dynamics, providing the spatial and temporal distribution of the dependent model variables and the various processes being parameterized.

Model Hierarchy

General circulation models of reduced complexity are continuously developed to supplement comprehensive

Figure 1. Interactions in comprehensive GCMs (schematic).

Figure 2. A model hierarchy of general circulation models.

GCMs, to gain insight into atmospheric phenomena (see Figure 2) and for educational purposes: when utilizing the full set of equations, the model spectrum ranges from simple GCMs (SGCMs) with analytic forms of heating and friction to low-order models (LOMs). A prominent LOM is the Lorenz model (See **Lorenz equations**), which approximately describes the nonlinear convection dynamics in the vicinity of a critical point for the stream function and temperature in a set of ordinary differential equations. It can be regarded as including first-order nonlinear effects (temperature advection) to a linear model, which leads to chaotic behavior. The Lorenz model is used to study predictability and serves as a paradigm for phase-space behavior of atmospheric GCMs. Utilizing thermal energy conservation only, another spectrum of models (energy balance models, or EBMs) is obtained by averaging in certain spatial

directions. This leads to the horizontally averaged one-dimensional radiative-convective models; the one-dimensional energy balance model when averaged vertically and longitudinally for studying climate feedback and stability; and two-dimensional statistical-dynamical models when averaged longitudinally where dynamical processes are being parameterized. A prominent EBM example is the globally averaged or zero-dimensional energy balance model. With ice-albedo and water vapor-emissivity feedbacks included, climate catastrophes leading to a snowball earth and runaway greenhouse can be demonstrated. With random forcing and periodic solar radiation input (e.g., Milankovich cycles), stochastic resonance emerges.

GENERAL RELATIVITY

Called *general relativity*, Albert Einstein’s theory of gravitation was created as a generalization of his special relativity theory. As special relativity is a theory of physical space-time (neglecting gravitational effects), general relativity is a theory of physical space-time in the presence of gravitation.

While Maxwell’s theory of electromagnetism is a relativistic theory that is covariant with respect to Lorentz transformations, Newton’s theory of gravitation is incompatible with special relativity. In 1907,

two years after proposing special relativity, Einstein was preparing a review of special relativity when he suddenly wondered how Newtonian gravitation would have to be modified to fit in with special relativity. Einstein described this as “the happiest thought of my life.” He proposed the *equivalence principle* as “the complete physical equivalence of a gravitational field and the corresponding acceleration of the reference frame” that “extends the principle of relativity to the case of uniformly accelerated motion of the reference frame.”

In fact, Einstein’s equivalence principle is a generalization of the so-called *weak* equivalence principle, which dates from Galileo and Newton and states that the inertial mass and gravitational mass of any object are equal. Thus (neglecting friction), the acceleration of different bodies in a gravitational field is independent of their masses and other physical characteristics, and hence, with given initial conditions, their motions will be the same.

The next important step was made by Einstein in his 1912 papers, where he concluded that “if all accelerated systems are equivalent, then Euclidean geometry cannot hold in all of them.” Further investigations by Einstein to find the correct form of equations for a gravitational field were connected with applications of Riemannian geometry and tensor analysis. The final form of equations of general relativity was given by Einstein in his paper “The Field Equations of gravitation,” submitted on 25 November 1915. At about the same time, David Hilbert submitted a paper entitled “Foundations of Physics,” which also contains the correct field equations for gravitation, introduced by applying a variation principle.

Physical Space-time and Gravitating Matter in General Relativity

According to general relativity, physical space-time in a gravitational field is non-Euclidean; so to describe the properties of space-time, Einstein applied Riemannian geometry. Without gravitation, physical space-time is a flat pseudo-Euclidean Minkowski 4-continuum, where free particles move uniformly and linearly along geodesic worldlines of Minkowski space-time. Einstein’s key idea is that in a gravitational field, particles move along geodesic lines of curved space-time, and in accordance with the Equivalence principle, their movement does not depend on the particles’ characteristics. Thus, motion for an observer is motion along curves in 3-space with variable velocity. Curvature of space-time in general relativity is created by sources of gravitational field. In general relativity, the role of sources of gravitational field is played by the energy-momentum tensor describing the distribution and motion of gravitating matter. Energy (or mass) density (the source of gravitation in Newton’s theory) is only a component of the energy-momentum

tensor. Besides energy (mass), a gravitational field in general relativity is also created by momentum and other components of an energy-momentum tensor. The dependence between geometrical properties of physical space-time and gravitating matter is described by Einstein’s gravitational equations.

Einstein Gravitational Equations

The principal geometrical characteristics of a gravitational field in general relativity are given by the metric tensor g_{ik} , which determines the square of distance between two infinitesimally close points of pseudo-Riemannian 4-space-time

$$ds^2 = g_{ik} dx^i dx^k \quad (i, k = 0, 1, 2, 3). \quad (1)$$

By means of the metric tensor, time intervals and spatial distances can be defined; thus the formula for proper time fixed by a clock at rest in some reference frame is $d\tau = (1/c)\sqrt{g_{00}} dx^0$. Because the value of g_{00} in a gravitational field depends on location, time flow depends on gravitational field.

Einstein’s gravitational equations are nonlinear second-order differential equations with respect to the metric tensor and have the form

$$R_{ik} - 1/2 g_{ik} R = 8\pi G/c^4 T_{ik}, \quad (2)$$

where R_{ik} is the so-called Ricci tensor (a contraction of the curvature tensor), R is the scalar curvature, T_{ik} is the energy-momentum tensor, G is Newton’s gravitational constant, and c is the velocity of light in a vacuum. Einstein’s equations are covariant with respect to arbitrary coordinate transformations.

Equation (2) can be changed by adding to the right-hand side, the so-called cosmological term Λg_{ik} , where Λ is a cosmological constant introduced by Einstein. This term describes energy density and pressure of the vacuum, and it plays an essential role in cosmology, leading to the effect of gravitational repulsion if $\Lambda > 0$. In the case of weak gravitational fields, when the variation of metric with respect to the Minkowski metric is small, the Einstein equations lead to Newton’s law of gravitational attraction and allow one to find first relativistic corrections. In the case of strong gravitational fields, Einstein equations can give new physical results, including black holes and gravitational waves.

Experimental Verification and Bounds of Applicability

Several classical effects of general relativity have been verified observationally, including the bending of light in a gravitational field, gravitational redshift, the advance of the perihelion of the planet Mercury (43 s

of arc per century), and retarding of the propagation of light in a gravitational field. The first three effects were discussed by Einstein even before the creation of general relativity.

The *weak* equivalence principle has been verified to high precision (10^{-12}), and general relativity provides a basis for relativistic astrophysics and cosmology. The Hot Big Bang model was built within the framework of general relativity. Over the past two decades, the role of general relativity has grown in connection with discoveries in cosmology—in particular, acceleration of cosmological expansion, dark matter and dark energy, and other problems that need to be resolved.

General relativity is a classical theory, and a consistent quantum theory of gravitation has not yet been developed. In fact, the formulation of a quantum-gravitation theory requires a unified theory of all fundamental physical interactions. At present, the most popular candidate for such a unified theory is the superstring theory. This theory is in higher-dimensional space, and it leads to a generalization of Einstein's gravitation theory. A second problem with general relativity is the presence of gravitational singularities (cosmological singularities, collapsing systems, etc.). According to theorems by Stephen Hawking and Roger Penrose, this problem is connected under certain conditions with internal properties of the gravitational equations of general relativity. As with classical theory, general relativity is inapplicable near singular states.

The creation and development of Einstein's gravitation theory was a triumph of 20th-century science, providing the basis of gravitation theory, relativistic astrophysics, and cosmology. Within the frame of its applicability, general relativity will remain a great achievement of human culture.

GENERALIZED FUNCTIONS

Generalized functions were introduced into quantum mechanics by Paul Dirac, who defined the delta function $\delta(x)$ as follows (Dirac, 1958):

$$\delta(x) = 0 \text{ for } x \neq 0$$

and

$$\int_{-\varepsilon}^{+\varepsilon} \delta(x) dx = 1 \text{ for } \varepsilon > 0. \quad (1)$$

Although $\delta(x)$ is not a true function (from a mathematical perspective) because it is undefined at $x = 0$, the delta function is widely used in physics to approximate functions that are localized in space or time. Examples of such idealizations include the concepts of point mass or point charge and the spatially localized action of a pick on a guitar string.

In an engineering context, the delta function is called the unit impulse function and is used to approximate functions of large amplitude and short duration such as the striking of a golf ball or the instantaneous charging of an electrical capacitor (Guillemin, 1953). Since such point sources are only idealizations, they can be represented by the limiting procedure, $\delta(x) = \lim_{a \rightarrow \infty} \delta_a(x)$ for a family of piecewise continuous functions $\delta_a(x)$, where a is a continuous parameter. Among others, the following four functions, $\delta_a(x)$, are popular approximations of the delta function $\delta(x)$ (Pauli, 1973):

- *Unit impulse (box)*: $\delta_a(x) = a/2$ for $|x| < 1/a$, and $\delta_a(x) = 0$ for $|x| > 1/a$.
- *Finite impulse response filter*: $\delta_a(x) = \sin ax/\pi x$.
- *Gaussian pulse*: $\delta_a(x) = ae^{-\pi a^2 x^2}$.
- *Lorentzian pulse*: $\delta_a(x) = a/(1 + \pi^2 a^2 x^2)$.

In the limit $a \rightarrow \infty$, all representations $\delta_a(x)$ have zero width, infinite peak amplitude, and unit area, that is, all the approximations converge to the delta function $\delta(x)$ (see Figure 1).

Closely related to Dirac's delta function is Oliver Heaviside's step function, which was introduced in the late 19th century and has been widely used in electronics and communications research since the 1920s (Heaviside, 1950; Guillemin, 1953). The Heaviside step $H(x)$ is defined as follows:

$$H(x) = 1 \text{ for } x > 0 \text{ and } H(x) = 0 \text{ for } x < 0. \quad (2)$$

The derivative of the Heaviside step function is recognized as Dirac's delta function because $H'(x) = 0$ for $x \neq 0$ and for $\varepsilon > 0$

$$\int_{-\varepsilon}^{+\varepsilon} H'(x) dx = H(+\varepsilon) - H(-\varepsilon) = 1. \quad (3)$$

Figure 1. Approximations of the Dirac delta function $\delta(x)$ for $a=1$ (dotted curves) and $a=3$ (solid curves): (a) the box, (b) the impulse response filter, (c) the Gaussian pulse, and (d) the Lorentzian pulse.

In engineering terms, the step function represents an instantaneous jump from zero to unit value of some physical quantity such as the signal voltage at the input terminals of an amplifier.

Because the delta and step are not defined at $x=0$, they are not true functions; thus mathematicians call them distributions, implying rules that assign numbers to integral expressions (Strauss, 1992). To understand this perspective, consider a real function, $f(x)$ which has derivatives for all values of x that approach zero faster than any power of x . In other words, $\lim_{|x| \rightarrow \infty} |x|^p f^{(m)}(x) = 0$ for any $m \geq 0$ and $p \geq 0$. Such functions $f(x)$ are called test functions for integral distributions. As is seen from the box approximation of $\delta_a(x)$ in the limit $a \rightarrow \infty$, the delta function $\delta(x)$ assigns the number $f(0)$ to the integral distribution associated with a test function $f(x)$:

$$\int_{-\infty}^{\infty} f(x) \delta(x) dx = f(0). \quad (4)$$

More generally, the delta function $\delta(x)$ and its derivatives $\delta^{(m)}(x)$ satisfy the following fundamental property:

$$\begin{aligned} & \int_{-\infty}^{\infty} f(x) \delta^{(m)}(x - \xi) dx \\ &= (-1)^m \int_{-\infty}^{\infty} f^{(m)}(x) \delta(x - \xi) dx \\ &= (-1)^m f^{(m)}(\xi), \end{aligned} \quad (5)$$

where $f(x)$ is a test function. A brief list of useful delta function properties follows from the fundamental

property in Equation (5) (Gel'fand & Shilov, 1964):

- *Even function:* $\delta(-x) = \delta(x)$.
- *Scaling transformation:* $|\xi| \delta(\xi x) = \delta(x)$.
- *Factorization:* $2|\xi| \delta(x^2 - \xi^2) = \delta(x - \xi) + \delta(x + \xi)$.
- *Projection formula:*

$$\frac{1}{(x - \xi \mp i0)} = \text{PV} \left[\frac{1}{(x - \xi)} \right] \pm \pi i \delta(x - \xi) \quad (\text{where PV stands for principal value}).$$
- *Fourier transform:* $\delta(k) = \int_{-\infty}^{\infty} \delta(x) e^{-ikx} dx = 1$.
- *Spectral representation:* $2\pi \delta(x) = \int_{-\infty}^{\infty} e^{ikx} dx$.

Dirac studied orthogonality relations for the wave function $\psi_\lambda(x)$ of the stationary Schrödinger equation with a potential

$$-\frac{\hbar}{2m} \psi_\lambda''(x) + U(x) \psi_\lambda(x) = \lambda \psi_\lambda(x). \quad (6)$$

In this context, square integrable wave functions for different levels of energy λ are orthogonal with respect to the inner product

$$\langle \psi_{\lambda'} | \psi_\lambda \rangle = \int_{-\infty}^{\infty} \bar{\psi}_{\lambda'}(x) \psi_\lambda(x) dx = \delta_{\lambda', \lambda}, \quad (7)$$

where $\delta_{\lambda', \lambda} = 0$ for $\lambda' \neq \lambda$ and $\delta_{\lambda, \lambda} = 1$. Similar orthogonality relations for wave functions of continuous spectra diverge. For example, linear waves in free space (when $U(x) = 0$) take the form $\psi_\lambda(x) = \Psi(x; k) = e^{ikx}$ for $\lambda = \hbar k^2/2m$. They are periodic in x with period $L = 2\pi/k$. If $k = k_n = 2\pi n/L$, the periodic function satisfies the following orthogonality relations on the finite interval $x \in [-L/2, L/2]$:

$$\langle \Psi(k_{n'}) | \Psi(k_n) \rangle = \int_{-L/2}^{L/2} e^{i(k_n - k_{n'})x} dx = L \delta_{n', n}. \quad (8)$$

When linear waves in free space are taken over the whole real axis (i.e., $L \rightarrow \infty$), the inner product of the wave function $\Psi(x; k)$ with itself diverges. The delta function $\delta(k)$ replaces this divergence in the closed form

$$\begin{aligned} \langle \Psi(k') | \Psi(k) \rangle &= \int_{-\infty}^{\infty} \bar{\Psi}(x; k') \Psi(x; k) dx \\ &= 2\pi \delta(k' - k), \end{aligned} \quad (9)$$

where $\delta(k) = 0$ for $k \neq 0$ and $\delta(0) = \infty$. The singularity of the delta function $\delta(k)$ is uniquely specified in the distribution (integral) sense by requiring that

$$\int_{-\infty}^{\infty} \delta(k) dk = 1. \quad (10)$$

The delta function $\delta(x)$ represents not only the orthogonality of the wave functions $\psi_\lambda(x)$ of

the stationary Schrödinger equation, but also their completeness with the completeness relation:

$$\frac{1}{2\pi} \int_{-\infty}^{\infty} \bar{\Psi}(x'; k) \Psi(x; k) dk + \sum_n \bar{\Psi}_n(x') \Psi_n(x) = \delta(x' - x), \quad (11)$$

where $\Psi(x; k)$ are wave functions of the continuous spectrum and $\Psi_n(x)$ are wave functions of the discrete spectrum. With the use of the delta function $\delta(x)$, a test function $f(x)$ can be expanded into a complete and orthogonal set of wave functions:

$$f(x) = \frac{1}{2\pi} \int_{-\infty}^{\infty} \hat{f}(k) \Psi(x; k) dk + \sum_n \hat{f}_n \Psi_n(x), \quad (12)$$

where coefficients of the expansion are

$$\hat{f}(k) = \langle \Psi(k) | f \rangle, \quad \hat{f}_n = \langle \Psi_n | f \rangle. \quad (13)$$

Generalized functions are widely used in electric circuit theory, communications, spectral analysis, integral transforms, and Green function solutions of equations of mathematical physics (Guillemin, 1953; Pauli, 1973; Strauss, 1992). For example, the Fourier transform is based on the spectral decomposition above for $\Psi(x; k) = e^{ikx}$ and $\Psi_n(x) = 0$.

GEOMETRICAL OPTICS, NONLINEAR

Nonlinear geometric optics arose in the second half of the 20th century in several areas of research, including nonlinear optics and reaction-diffusion systems. To understand the origin of such problems and the underlying physical phenomena, it is helpful to consider briefly the historical path that has led to them.

Classical Results

Traditionally, geometric optics comprised all of optics. It developed from empirical laws of propagation for

light beams, which are bent in a non-uniform medium and refract and reflect at the interfaces of media possessing different optical properties. Remarkable successes were achieved, including inventions of the microscope and the telescope around the beginning of the 17th century. At the same time, some important scientific problems were studied; thus in 1620, Willebrord Snell established the law of refraction at the interface of two transparent media. Assuming angles are measured with respect to a line normal to the boundary, Snell's law states that at any angle of incidence (ψ_1), the ratio

$$\frac{\sin \psi_1}{\sin \psi_2} = \text{constant} \equiv n_{12}, \quad (1)$$

where ψ_2 is the angle of refraction and the constant n_{12} is the reciprocal refractive index. Interestingly, this important law was independently discovered by René Descartes about a decade later. Pierre Fermat's subsequent formulation of the principle of least time—which governs the propagation of light rays—completed the phenomenological theory of geometric optics.

In the 17th century, two competitive hypotheses were advanced for the physical nature of light: the corpuscular hypothesis of Isaac Newton and the wave theory of Christian Huygens. Two centuries later, after the theoretical studies and experimental works of Thomas Young, Augustin-Jean Fresnel, and François Arago, the wave theory of light triumphed. The true nature of light was revealed in the 19th century to be based on James Clerk Maxwell's theory of electromagnetism, which predicted the existence of electromagnetic waves that propagate in vacuum with constant velocity $c = 1/\sqrt{\epsilon_0 \mu_0} \approx 3 \times 10^8$ m/s, where ϵ_0 and μ_0 are the dielectric permittivity and magnetic permeability of vacuum, respectively.

This value—obtained entirely from independent measurements of electric and magnetic fields—is precisely equal to the light velocity in vacuum, which was first measured by Ole Roemer two centuries before (using astronomical data on time intervals between eclipses of Jupiter's satellites). Together with the subsequent experimental discovery and investigation of properties of electromagnetic waves inspired by Hermann Helmholtz and performed by Heinrich Hertz, this result has convinced physicists of the electromagnetic nature of light.

This electromagnetic theory of light explains most optical phenomena. For example, it yields Snell's law of refraction, giving the constant in Equation (1) as

$$n_{12} = v_1/v_2 = \sqrt{\epsilon_2/\epsilon_1} = n_2/n_1. \quad (2)$$

Here v_i is the velocity of light in the i th medium ($i = 1, 2$), and ε_i and $n_i = c/v_i = \sqrt{\varepsilon_i/\varepsilon_0}$ are the dielectric permittivity and the absolute refractive index of this medium, respectively.

Physical mechanisms underlying the refractive index were studied by Helmholtz, Paul Drude, and Hendrik Lorentz at the close of the 19th century. They merged the electromagnetic theory with the idea of electrons as charged particles bound in atoms and molecules which are dislocated under the influence of an electromagnetic field of a light wave. (From the modern point of view, such electrons occupy exterior atomic shells; thus, they are referred to as optical electrons.) Further developments of such ideas connect optical phenomena with the dynamic response of an optical medium to the electromagnetic waves propagating through it.

When a light wave propagates through a dielectric medium, its electric field ($\mathbf{E}$) displaces the optical electrons, inducing a wave of electric polarization ($\mathbf{P}$). The latter generates a secondary electromagnetic wave which is added to the primary wave, modifying the polarization wave, and so on, ad infinitum. In other words, the electromagnetic wave and the response of an optical medium determine each other. As the relations

$$\begin{aligned}\varepsilon \mathbf{E} &= \varepsilon_0 \mathbf{E} + \mathbf{P}, & \mathbf{P} &= \varepsilon_0 \chi \mathbf{E}, \\ n &= c/v = \sqrt{\varepsilon/\varepsilon_0}\end{aligned}\quad (3)$$

are always fulfilled (where χ is the dielectric susceptibility of the medium), the absolute refraction index of the medium can be expressed via χ by the formula

$$n = \sqrt{\varepsilon/\varepsilon_0} = \sqrt{1 + \chi}. \quad (4)$$

If the light wave is sinusoidal and sufficiently weak, the response of the medium is readily calculated; thus the susceptibility χ is expressed via the oscillatory parameters of optical electrons which, in turn, depend on the frequency (ω), but not on the wave amplitude. Weakness of a light wave means that intensity $\mathbf{E}$ of an electric field in the wave must be much smaller than characteristic intensities of intra-atomic electric fields. The greatest intra-atomic intensities (reached in the hydrogen atom) are about 5×10^9 V/cm, whereas the intensities of light fields generated by ordinary (nonlaser) sources of light are about 1 V/cm. Thus, the constitutive equation relating the electric polarization $\mathbf{P}$ with the electric field intensity $\mathbf{E}$ is linear for ordinary light.

Nonlinear Optics

In the latter half of the 20th century, lasers were invented, which could generate fields with intensities of about 10^7 V/cm, and in 1989, beams of light were

produced with electric fields of more than ten times the intra-atomic values. In such strong fields, dielectric susceptibility χ becomes dependent on the electric field intensity, making the constitutive equation nonlinear. Both the dielectric permittivity ε and the absolute refraction index n of the medium also depend on the electric field intensity $\mathbf{E}$, and these dependencies are modified by additional influences, such as heating of the medium.

Studies of optical effects in strong light fields use the basic ideas of geometric optics, for example, the concept of refractive index. Consider a uniform isotropic dielectric medium. Adverting to Equation (3), let us write the expansion

$$\mathbf{P} = \varepsilon_0 \chi^{(1)} \mathbf{E} + \varepsilon_0 \chi^{(2)} |\mathbf{E}|^2 + \varepsilon_0 \chi^{(3)} |\mathbf{E}|^2 \mathbf{E} + \dots \quad (5)$$

Here, even powers of $\mathbf{E}$ are excluded by symmetry consideration, so $\chi = \mathbf{P}/\varepsilon_0 \mathbf{E} = \chi^{(1)} + \chi^{(3)} |\mathbf{E}|^2 + \dots$, which implies (see Equation (4))

$$\begin{aligned}n &= \sqrt{1 + \chi^{(1)} + \chi^{(3)} |\mathbf{E}|^2} \approx n_0 + 2n_3 |\mathbf{E}|^2, \\ n_0 &= \sqrt{1 + \chi^{(1)}}, \quad n_3 = \frac{\chi^{(3)}}{4\sqrt{1 + \chi^{(1)}}},\end{aligned}\quad (6)$$

because the nonlinear term is small. Averaging n on the time period $T = 2\pi/\omega$ of oscillations of electric field $\mathbf{E} = \mathbf{E}_0(x, y, z) \sin \omega t$ yields

$$n = n_0 + n_3 |\mathbf{E}_0|^2, \quad (7)$$

where n_0 is the linear refractive index and $n_3 |\mathbf{E}_0|^2$ describes the nonlinear correction to this index.

Equations (3) and (7) indicate that a bounded cylindrical beam of light can create an optical heterogeneity in the medium through which it propagates. Suppose the beam is Gaussian so the amplitude of electric oscillations varies transversely as $|\mathbf{E}_0|(r) = A_0 \exp[r^2/(2r_0^2)]$, where A_0 is the value of amplitude on the axis of beam, r is distance from the beam axis, and r_0 is a phenomenological constant determining the typical width of the beam. Then,

$$\begin{aligned}v &= c/(n_0 + n_3 A_0^2) \quad \text{on the axis of the beam;} \\ v &= c/n_0 \quad \text{far from the axis of the beam.}\end{aligned}$$

If the inequality $n_3 > 0$ ($n_3 < 0$) is fulfilled, the axial velocity of light is smaller (greater) than the peripheral velocity. In first case, the plane wave front will become concave in the direction of light propagation, and self-focusing of the beam will occur; while in the second case, self-defocusing of the beam will occur. Both these phenomena have been observed; in particular, self-focusing was predicted by Gurgen Askarian in 1962 and then experimentally observed by N.P. Pilipetsky and A.R. Rustamov in 1965.

Nonlinear Reaction-Diffusion Systems

One can image an excitable medium (EM) as a spatial region G occupied by a medium, in which the processes of autocatalytic production, destruction, and diffusion of some substances occur. In the simplest case, when only one substance of concentration $u = u(\mathbf{r}, t)$ is involved (here $\mathbf{r}$ is a point in three-dimensional space and t is time), the dynamics of u are described by two relationships: the continuity equation

$$u_t + \operatorname{div} \mathbf{J} = f(u) \quad (8)$$

(where $u_t = \partial u / \partial t$), and the Fick diffusion law

$$\mathbf{J} = -D \operatorname{grad} u. \quad (9)$$

For constant diffusivity D , these two equations reduce to the single parabolic reaction-diffusion equation

$$u_t = D \Delta u + f(u). \quad (10)$$

Here, the symbols div , grad , and Δ designate the spatial divergence, gradient operator, and Laplace operator, respectively; $\mathbf{J} = \mathbf{J}(\mathbf{r}, t)$ is the vector of diffusion flux density of the substance; and the function $f(u)$ (called the kinetic function of the active medium) determines the dependence of the production/destruction rate of substance per unit volume of the concentration u .

In general, an EM is able to support the propagation of traveling-wave fronts and impulses. In the steady regime, plane excitation waves propagate with constant speed preserving their spatial profile. Both the speed and the wave profile are determined by physical parameters of the medium in which the waves propagate and are independent of initial conditions; thus such waves are called *autowaves* (AW). This term was coined by Rem Khokhlov (an early Russian specialist on nonlinear physics and president of Moscow State University) in a 1974 presentation as an official opponent during Anatol Zhabotinsky's defense of his doctoral thesis on periodic chemical reactions. (An enthusiastic mountain climber, Khokhlov sadly perished in the Caucasian mountains in 1977.) The significance of AWs stems from the fact that they frequently occur in physical, chemical and biological applications, including muscles, the nervous system, and the heart.

To reveal the qualitative properties of AW propagation, one needs to solve these equations; but even in the spatially homogeneous case—when the medium is described by Equation (10) with constant D —this problem is challenging. Thus, it is of interest to consider an approach in which the general properties of EM are specialized by means of some simple axioms. Interestingly, this approach leads to an analog of traditional

geometric optics, as was first shown by Israel Gel'fand and Sergei Fomin in 1961 (Gel'fand & Fomin, 1961).

When either a traveling-wave front or the leading edge of an impulse moves through an EM, the latter switches from the resting state to the excited state (in the case of impulse, the life time of excitable state is finite and equal to the pulse duration). Neglecting the front width, one may imagine the leading edge as a surface that separates the resting and excited zones, and a motion of this surface (which models the motion of an AW) is interpreted as propagation of excitation. Thus, Gel'fand and Fomin introduced two axioms: (i) each spatial point of the EM can be in one of two states: either in the resting state or in the excited one; (ii) if at some time moment t the excitation has reached some spatial point P , then P immediately becomes a source of propagating excitation. In the case of a nonhomogeneous anisotropic EM, the time period dt of motion of excitation along the infinitesimal path connecting the points $x(s)$ and $x(s + ds) = x(s) + (dx/ds) ds$ (here s is the parameter) depends both on the point $x(s)$ and on the vector $[dx/ds : dt = f(x, dx/ds) ds]$. The function $f(x, dx/ds)$ (which is assumed to be a strict convex function of the second argument) is a key element of the theory; thus, if the point $x_1 = x(s_1)$ is excited, then the time period after which the point $x_2 = x(s_2)$ will be excited is given by the expression

$$\min \int_{x_1}^{x_2} f(x, dx/ds) ds,$$

where the minimum is taken over all curves connecting the points x_1 and x_2 . (Indeed, if the excitation propagating from the point x_1 along all possible paths has already reached the point x_2 along some path, then all paths that connect x_1 and x_2 , but take more time, are insignificant.) This is equivalent to Fermat's principle of least time, adapted to dynamic processes in EM. Thus, Gel'fand and Fomin developed a variational theory of propagation of excitation, endowing it with proper Lagrange–Hamiltonian–Jacobi equations that are formally equivalent to the variational formalism of geometric optics based on Fermat's principle.

The Gel'fand–Fomin formulation follows earlier studies of cardiology by Norbert Wiener and Arturo Rosenbluth, whose system of axioms involves an additional (refractory) state (Wiener & Rosenbluth, 1946). Any point goes to the refractory state immediately upon being excited, after which it cannot be excited during the finite time period R . Supposing the velocity v of propagation of excitation to be constant, Wiener and Rosenbluth developed the theory of circulation of an excitation around non-excitable obstacles and determined the least critical length λ of the obstacle, around which the excitation can stationary circulate: $\lambda = Rv$. Further development of these geometric approaches was undertaken by

those involved in a seminar on mathematical biology (organized by Gel'fand at Moscow State University in the early 1960s) and led to a prediction of the existence of spiral waves (Balakhovsky, 1965).

Current geometric theories of spiral waves are concerned with properties that were long ignored, including the dependence of an AW leading-edge velocity on the curvature of the edge. Around 1980, Werner Ebeling, Yakov Zeldovich, Yoshiki Kuramoto, and Vladimir Zykov independently showed that the velocity of a curved leading edge must differ from the velocity of a plane edge—if the edge is concave (convex) in the direction of its propagation then it must accelerate (decelerate). This fact is readily understood in the case of a combustion wave where ignition occurs more rapidly (slowly) ahead of concave (convex) parts of the flame front than ahead of the plane parts due to focusing (diverging) the lines of heat flux. The formula for the velocity v of a weakly bent wave front that propagates in two-dimensional EM and obeys Equation (10) is

$$v = v_0 - DK, \quad (11)$$

where v_0 is the velocity of plane front and K is the curvature of the wave front. The domain of applicability of this equation is given by the inequality $Kl_f \ll 1$, where l_f is a characteristic width of the front.

Equation (11) implies that excitation of sufficiently small circular patches of EM will die out. The radii of such patches are bounded above by the critical value $\rho_c = |K_c|^{-1} = Dv_0^{-1}$ which corresponds to the zero value of v in Equation (11). In a more precise theory of curved AW dynamics (Kuramoto, 1980), Equation (11) emerges as an eikonal equation in the “nonlinear geometric optics” of an AW; thus, it is deeply involved in the modern geometric theory of spiral waves (Mikhailov et al., 1994; Elkin et al., 1998).

Interestingly, a version of Snell's law for AWs emerges from such studies which differs from that of classical optics in several important ways:

- Assuming the underlying reaction-diffusion equation to be Equation (10), Equation (1) is replaced by

$$\frac{\tan \psi_1}{\tan \psi_2} = \text{constant} = \frac{D_1}{D_2}, \quad (12)$$

where D_1 and D_2 are the diffusion constants in the incident and refractive regions.

- This is a *local* law which determines the structure of refracted concentration fronts only near the interface between homogeneous regions rather than far from it.
- Equation (12) is obeyed for nonstationary as well as stationary refractions.

- In the regime of stationary refraction, when the incident wave and the refracted one shape a planar form and move with constant velocities, the angles of incidence and refraction are determined by the conditions (Mornev, 1984)

$$\sin \psi_1 = \sqrt{D_1/(D_1 + D_2)}$$

and

$$\sin \psi_2 = \sqrt{D_2/(D_1 + D_2)}.$$

If a plane AW is normally incident on the boundary ($\psi_1 = 0$) and D_2 is sufficiently larger than D_1 , the wave will be forced to stop. Assuming $f(u)$ to be a cubic-shaped function possessing three zeroes $u_0 < u_b < u_1$ and satisfying the conditions $f(u) > 0$ at $(u < u_0)$ and $(u_b < u < u_1)$, $f(u) < 0$ at $(u_0 < u < u_b)$ and $(u > u_1)$, the condition for the AW to die at the boundary is

$$\frac{D_2}{D_1} > \frac{\sigma_+}{\sigma_-},$$

where σ_- (σ_+) denotes the least (greatest) of two values $|\int_{u_0}^{u_b} f(u) du|$, $|\int_{u_b}^{u_1} f(u) du|$ (Mornev, 1984).

GEOMORPHOLOGY AND TECTONICS

Geomorphology deals with the evolution of Earth's surface by gravity (e.g., landslides) and the sculpting

action of wind, river flow, and ice. Tectonics deals with the deformation and uplift of rocks, including the behavior of earthquakes. Nonlinearity arises in many geomorphic systems in the feedbacks between the shape of the surface and the fluid flow above the surface. The shapes of sand ripples and dunes, for example, control the flow of wind above the surface, which, in turn, controls the spatial distribution of erosion and deposition. Over time, erosion and deposition modify the shape of the surface and the flow of wind in a positive feedback loop. The flow of wind over a dune and the sediment transport caused by the wind are both nonlinear processes. The relationship between the sediment flux moved by the wind over a dune, for example, and the shear stress exerted by the wind is strongly nonlinear, including both a threshold shear stress for particle entrainment and a nonlinear power-law relationship between flux and shear stress above that threshold.

Some of the nonlinear feedback relationships in geomorphic systems affect practical issues. The feedback between vegetation density and soil erosion, for example, can lead to dust bowl conditions if low vegetation density promotes wind erosion, stripping the soil to further inhibit vegetation growth in a positive feedback loop. In tectonic systems, nonlinear feedbacks also govern much of the interesting behavior. Deformations in rock or along a fault plane, for example, can become localized by the feedback between shear strength and strain rate. Rocks often become weaker as they are strained, in turn focusing more deformation to the areas of highest strain. The rheology of rocks, including their nonlinear dependence on strain rate and time, thus plays a very important role in our understanding of mountain belts.

Self-organized, periodic landforms have received considerable attention in geomorphology. Sand ripples, dunes, and yardangs (all examples of eolian landforms), flutes (elongated ridges of subglacial sediment), drumlins (sculpted large mounds of subglacial debris), finger lakes, cirques, sorted stone stripes and circles (all glacial and periglacial landforms), discontinuous ephemeral streams and step-pool sequences (fluvial landforms), beach cusps and spits (coastal landforms) all have a characteristic width or spacing (Figure 1) that is controlled in part by the fluid movement on or above the surface and its relationship to erosion and deposition. The dynamic processes governing these systems are disparate and complex, but feedback between the surface and the fluid flow on or above the surface plays a key role in all of these examples. Finger lakes, for example, are elongated glacial troughs that developed on the margins of former ice sheets as glacier flow was focused into incipient bedrock depressions, concentrating glacial erosion in troughs in a positive feedback that forms deeper basins when the ice retreats. The Finger Lakes of central New York are the

Figure 1. Sand ripples with a characteristic width or spacing. White Sands, New Mexico, courtesy of National Park Service.

typical examples, but similar lakes occur along other former ice margins. Step-pool sequences form in mountain river channels by feedback between the roughness of the channel bed, the flow velocity in the channel, and the selective entrainment of particles on the bed. A channel reach with an initially rougher bed than nearby reaches will have slower flow velocity, promoting the deposition of coarse particles along the channel reach and a further decrease in flow velocity. This feedback produces channel reaches characterized by shallow gradients and fine particles alternating with steep gradients and coarse particles. In some cases, numerical models have been developed that enable the wavelengths of these periodic landforms to be predicted.

In many if not most cases, landform evolution does not lead to periodic topography at all. River networks, coastal erosion of a rugged shoreline, and the dissolution of limestone to form cave networks (or karst topography above ground) are all examples of processes that create chaotic landforms with no apparent characteristic scale. Many of these landforms have an underlying order, however, by virtue of their self-similarity. Self-similar landforms are those that have a similar appearance and statistical structure at a wide range of spatial scales. Rugged coastlines are the classic example of fractals popularized by Benoit Mandelbrot (1982). Long before the fractal structure of coastlines had been described, however, geomorphologists were interested in the self-similarity of river networks. To examine this self-similarity, streams are first ordered according to their position in a drainage network. The Strahler order defines all channels with no upstream tributaries as first-order channels. Whenever any two streams of like order join at a tributary, they form a stream of the next highest order. Horton's law states the principle of self-similarity of drainage networks mathematically: the ratio of the number of streams of order n to the number of streams of order $n + 1$ is equal to approximately 4 and is independent of n (Rodríguez-Iturbe and Rinaldo (2001) provide an excellent review). Similar relationships exist between channel lengths, areas, and the Strahler order.

Horton's laws are satisfied in many different kinds of networks; however, so the modern view is that Horton's laws are not unique properties of drainage networks (Kirchner, 1993). Other relationships, such as the angles of tributary junctions and the relationships between channel slope and the Stahler order, contain important information about the self-organization of channel networks.

The Earth's crust exhibits nonlinear, critical behavior in several ways. First, earthquakes occur over a wide range of sizes with a frequency-size distribution characterized by a power law. This observation, known as the Gutenberg–Richter law, is the most fundamental rule of seismology. Seismicity also exhibits temporal correlations that have self-similar properties. Omori's law, for example, states that the frequency of foreshocks or aftershocks is inversely proportional to the time before or since the mainshock. Theoretical models for fault behavior have been devised based upon a simple model of blocks (representing one fault plane) frictionally coupled to a table (the other fault plane) and elastically coupled to one another and to a driver plate (representing the regional tectonic stress) (e.g., Turcotte, 1997). The model builds up stress until all the elements are near the threshold for slipping. At that point, the slippage of one block can transfer stress to other blocks in a cascade that produces earthquakes that follow the Gutenberg–Richter law. This phenomenon is called stick-slip friction. The discrete nature of the slider-block model appears to have an analog in real faults; the behavior of faults can be characterized according to the size and strength of asperities (sticky spots) on the fault plane, which are like the individual blocks in the slider-block system. The aftershock behavior of earthquakes does not appear to arise naturally in the simplest slider-block models; instead, some viscous coupling between blocks is necessary to reproduce Omori's law (Pelletier, 2000), suggesting that the punctuated process of seismic events is linked to a steady, creeping motion of the fault motion over longer time scales.

The crust also exhibits nonlinear critical behavior in the way that magma makes its way through the crust and is released as volcanic eruptions. The frequency-size distribution of volcanic eruptions appears to follow a power-law distribution analogous to the Gutenberg–Richter distribution in terms of the volume of material released. Magmatic and volcanic activity is also clustered in time in a way that is generally analogous to Omori's law. The processes of fluid movement through the crust are very different compared with the stresses on an earthquake fault, but a model for the spatial interaction of many fluid conduits all near the threshold for eruption produces a model very similar to the slider-block model (Pelletier, 1999). This kind of model appears to be most consistent with the Rayleigh distillation model of geochemical mixing

(Turcotte, 1997), which describes the abundances of certain geochemical elements in the crust.

GESTALT PHENOMENA

The Gestalt idea was introduced to science by Ernst Mach (1868) and Christian von Ehrenfels (1890). Mach stated that the spontaneous creation of order, that is, order arising without any external control, can be shown in inanimate nature. Von Ehrenfels characterized Gestalt qualities, that is, higher order qualities emerging from basic elements, by two criteria: (1) supersummativity, which means that the elements of a pattern presented individually to a person give, in the totality of the experience, a poorer impression than the total experience of a person to whom all the elements are presented; and (2) transposition, which means the characteristics of a Gestalt quality are retained even if all the elements which exhibit the Gestalt quality are changed in a certain way (for example, the transposition of a melody).

Wolfgang Köhler (1920) delivered the earliest formulation of a concept of self-organization of perception. The idea that perception must necessarily be understood as a process of autonomous creation of order runs through all his works. Starting from the observation of spontaneous Gestalt tendencies in experience, Köhler made it his primary task to design and test a model of brain function in which the phenomenal organization of the perceptual world is explained as not only stimulus-dependent, but as strongly dependent upon the perceptual system's own inner dynamics. In the development of Gestalt theory, Köhler was mainly oriented to the observations

and theoretical concepts of physics. In accordance with the assumption of linear thermodynamics, the general systemic tendency towards final equilibrium was considered in Köhler's time to be the only basic principle of self-organization. This principle can easily be demonstrated in cognition by recursive experiments of serial reproduction of complex patterns. These patterns follow the "principle of prägnanz" towards very simple and stable configurations (Stadler & Kruse, 1990; Kanizsa & Luccio, 1990). In perception, this principle states that people will perceive the most orderly or regular thing they can out of the stimuli that are presented to them. Köhler applied the model of physical fields striving independently to balance forces directly to the way in which the visual system functions. At the time, this almost provocatively contradicted the findings of neuroanatomy and neurophysiology. On the basis of his theoretical model of perception, the brain is not seen as a complex network of many different interacting neurons but as a homogeneous conductor of bioelectric forces.

Köhler's argument was not primarily the postulation of electromagnetic field forces acting in the brain independently of neuroanatomical structures (which has been refuted by most contemporary brain scientists) but the idea of self-organization in the brain. He was fully aware of the fact that the general principle of development of linear thermodynamics has been rather unsuitable for application to biological systems as long as it was oriented exclusively towards the final equilibrium. This was criticized by Köhler himself in 1955: "Although this is a perfectly good principle, it cannot, in its present formulation, be applied to the organism. For the organism is obviously not a closed system; moreover, while the direction indicated by the principle may be called 'downward', the direction of events in healthy organisms is on the whole clearly not 'downward' but, in a good sense, 'upward'."

Modern Developments

The brain is conceived as a self-organizing system that can be treated by means of synergetics (Haken, 1983, 1990). Pattern recognition is understood as pattern formation (of activities of the neural net). Incomplete (visual) data are complemented by a dynamic associative memory. In both cases (pattern formation and recognition), incomplete data generate order parameters that compete with each other. In general, one order parameter wins and generates, according to the slaving principle of synergetics, the complete pattern. In this processes, idealized (Gestalt) patterns may be incorporated. Of particular interest are ambiguous figures, such as Figure 1 (young woman vs. old woman). Here, two or more interpretations (percepts) are possible, and two (or more) order

Figure 1. Young woman vs. old woman.

parameters may win the competition. The final outcome is determined by an order parameter dynamics in which the dynamics of attention parameters is included.

The mathematical approach (algorithm of the "synergetic computer") is as follows: The images of different objects are decomposed into their pixels that are lumped together as pixel vectors

$$v_\mu = (v_{\mu 1}, v_{\mu 2}, \dots, v_{\mu N}), \quad \mu = 1, \dots, M. \quad (1)$$

The label μ is associated with an interpretation (the name of a person, say), and the adjoint vectors v_μ^+ are defined by

$$(v_\mu^+ v_\nu) = \delta_{\mu\nu}. \quad (2)$$

The activity pattern of the neural net is written as

$$q(t) = \sum_{\mu=1}^M \xi_\mu(t) v_\mu + r(t), \quad (3)$$

where r is a residual term that vanishes in the course of time. The order parameters are defined by

$$\xi_\mu(t), \quad (4)$$

where the initial value at the observation time t_0 is given by

$$\xi_\mu(0) = (v_\mu^+ q(0)). \quad (5)$$

The order parameters obey competition equations that can be derived from a potential function V

$$d\xi_\mu(t)/dt = -\partial V/\partial \xi_\mu, \quad (6)$$

where

$$V = V(\xi_1, \dots, \xi_M; \lambda_1, \dots, \lambda_M) \quad (7)$$

does not only depend on the order parameters but also on the attention parameters λ_j . The competition equations read explicitly

$$d\xi_\mu(t)/dt = \left(\lambda_\mu - B \sum_{\mu' \neq \mu}^M \xi_{\mu'}^2 - D \sum_{\mu'=1}^M \xi_{\mu'}^2 \right) \xi_\mu \quad (8)$$

with positive constants λ_μ, B, C . The winning order parameter fixes the activity pattern (3). In the case of ambiguous patterns (such as that of Figure 1), equations for the order parameters ξ_1 and ξ_2 and the attention parameters read

$$d\xi_1/dt = (\lambda_1 - C\xi_1^2 - (B+C)\xi_2^2)\xi_1 - \partial V_b/\partial \xi_1, \quad (9)$$

$$d\xi_2/dt = (\lambda_2 - C\xi_2^2 - (B+C)\xi_1^2)\xi_2 - \partial V_b/\partial \xi_2, \quad (10)$$

$$d\lambda_j/dt = \gamma(1 - \lambda_j - \xi_j^2), \quad j = 1, 2. \quad (11)$$

The bias potential V_b is defined by

$$V_b = 2B\xi_1^2\xi_2^2 \left(1 - 4\alpha \frac{\xi_1^2 - \xi_2^2}{\xi_1^2 + \xi_2^2} \right). \quad (12)$$

The parameter α is determined by the percentage of that perception that is seen first. It also determines the relative length of the perception times that occur in the oscillatory motion of the order parameters ξ_1, ξ_2 that represent the switch from one percept to the other one and back again.

GINZBURG–LANDAU EQUATION

See **Complex Ginzburg–Landau equation**

GLACIAL FLOW

Glaciers are defined as multi-year features, consisting of snow and ice, which flow down-slope under the force of gravity. The broadness of this definition means that there exists a continuum of glaciers that ranges from small, multi-year snow patches with surface areas of the order of 100 square meters, to the Columbia Glacier in Alaska, with a surface area of over 1100 square kilometers (the District of Columbia would fit within its terminus). Yet, in spite of the broad range of features encapsulated in this definition, the same basic physical processes are common to all of the world's roughly 160,000 different glaciers, and most of these processes are nonlinear.

Glaciers deform under their own weight, behaving like highly viscous fluids. Mass input is greatest at the glacier's upper elevations where colder temperatures result in a greater percentage of precipitation falling as snow. Mass loss is greatest at the glacier terminus, the lowest point on the glacier, where temperatures and melting are highest and where ablation (mass loss from melting, evaporation, sublimation, and in special cases, iceberg formation) equals flow. This imbalance results in a continuous mass transfer from the upper reaches to the lower reaches. The basis of the equations governing glacial flow is therefore mass conservation. However, unlike liquid water, where an applied stress, τ , (i.e., a squeeze) causes a linear, proportional deformation or strain, glaciers have a nonlinear stress-strain response. Although measurements in remote mountain locations are difficult and limited, field studies and laboratory experiments have shown that

$$\dot{\epsilon} = A\tau^n, \quad (1)$$

where n is constant and generally assigned a value of 3 (though values ranging from 1.5 to 4.2 can be found

in the literature), $\dot{\epsilon}$ is the rate of deformation, and $1/A$ is a nonlinear measure of the viscosity. This glacier "flow law" is a version of pseudoplastic flow and is similar to dry sand dune flows (which use a value of 2 for n). Viscoplastic flows, such as clay-water mixtures, and Bagnold macro-viscous flows, such as mud-flows, are also similar, differing primarily in the value of the exponent n .

The nonlinear flow law is the source of many fractal, self-similar, and nonlinear scaling properties. The basic scaling relationships are simple: discharge of ice through a given cross section of the glacier is proportional to glacier depth raised to the power $(n + 2)$, and glacier flow velocity is proportional to glacier depth raised to the power $(n + 1)$ (Patterson, 1994). However, Bahr (1997) has shown that in conjunction with mass and momentum conservation, the nonlinear flow law implies nonlinear scaling relationships between surface area (a parameter easily measured with satellites) and many difficult to measure but fundamental properties. Glacier thickness, volume, mass balance, velocity, flux, and other parameters relate to the surface area by exponents of $3/8$, $11/8$, etc. Using these unusual scaling exponents, the volume of ice in the world's glaciers can be predicted based solely on observed surface areas.

Equation (1) applies to basic glacier flow under constant stress. In reality, glaciers are rarely under consistent stress throughout. In areas where glaciers are under tensional stress, if the stress becomes too high, the ice becomes brittle and fractures, resulting in crevassing. Crevassing can be mathematically described using fracture mechanics (Smith, 1976; Sassolas et al., 1995). Crevassing can occur as the glacier flows over large drops in the bed as a result of varying flow speeds (Harper et al., 1998). Particularly dramatic crevassing occurs in the lower reaches of retreating tidewater glaciers as a result of faster flow at the glacier terminus than in the ablation zone (the area of the glacier that is annually losing more mass than it is gaining). Because the lower sections of tidewater glaciers are near or at floatation, unlike land-based glaciers, tidewater glacier crevassing can result in calving (the formation of icebergs from pieces that are broken off the terminus). Calving from tidewater glaciers can be modeled using both fracture mechanics and percolation theory (Bahr, 1995).

Tidewater glacier calving contributes to an unexpected nonlinearity in the tidewater glacier terminus position. Most glaciers move back and forth with changes in climate as the balance between melt and accumulation shifts. For tidewater glaciers, however, there is an additional loss of mass through calving. The tidewater glacier calving rate increases with water depth, but water depth is typically minimized by a pile of debris deposited at the end of the glacier. If the glacier terminus retreats backwards off the debris pile, then the water

depth increases and the calving rate increases, further increasing glacier retreat (Meier, 1993; van der Veen, 2002). This is a classic positive feedback loop scenario, and is the cause of the dramatic and rapid retreats recently seen in many glaciers that terminate in water, such as the Columbia Glacier in Alaska and many of the New Zealand glaciers that terminate in lakes. While many of the world's glaciers are slowly retreating due to changes in climate, these tidewater glaciers retreat nonlinearly in response to even the smallest climatic perturbations.

In addition to surface and internal processes, such as flow and crevassing, glaciers exhibit nonlinear behavior in their basal processes. For temperate glaciers (those not frozen to their beds), glacial flow is a combination of ice deformation and sliding at the glacier bed. Motion tends to be stick-slip, very similar to the nonlinear slider-block models of earthquakes (Bahr & Rundle, 1996; Fischer & Clarke, 1997). This gives rise to the grinding of the underlying rock, plucking of rocks out of the bed, and deformation of the bed in places where it is a fine-grained matrix. Lubrication appears to increase flow rates, as it does in sub-surface faults (Patterson, 1994). At the extreme end of lubricated basal flow, we find surging glaciers. These glaciers appear to build up water and water pressure at the glacier bed. Some mechanism or pressure trigger allows this water to be periodically catastrophically released (the Variegated Glacier in Alaska, for example, surged in 1906, 1947, 1964–65, and 1982–83), resulting in rapid flow and over-extension of the glacier (Patterson, 1994).

Finally, the overall structure of large glaciers is fractal. Large glaciers, such as the Talkeetna and Columbia Glaciers in Alaska have multiple upper branches that coalesce into one outlet tongue, similar to a river system or branching tree. Measurements have shown that the structure is statistically self-similar with fractal dimensions ranging from roughly 1.6 for small- to mid-sized mountain glaciers, to 2.0 for large glaciers and space-filling ice sheets such as Greenland (Bahr & Peckham, 1996).

GLOBAL WARMING

Few modern scientific concerns have achieved such notoriety as the possibility of relatively rapid anthropogenic global warming through increased CO₂ emissions. This complex problem became a matter of considerable public attention during the 1980s, and during the 1990s, the first attempt was made at international management of the challenge (the Kyoto Protocol under the United Nations Framework Convention on Climatic Change). However, scientific awareness of CO₂-induced climatic change is not new, and the underlying physical processes were understood from the beginning of studies concerning the absorption of radiation by the atmosphere. Later research resulted in a deeper understanding of the dynamics of the biospheric carbon cycle, and global atmospheric circulation models have been adopted, and adapted, for assessing the future course of tropospheric CO₂ levels. In spite of all of these advances, much remains unclear and uncertain.

Early Studies

Several years before his death in 1830, the French mathematician Joseph Fourier concluded that the atmosphere acts like the glass of a greenhouse, letting light through and retaining the invisible rays emanating from the ground (Fourier, 1822). In modern scientific terms, the atmosphere is highly (though not perfectly) transparent to incoming (shortwave) solar radiation, but it is a strong absorber of certain wavelengths in the outgoing (longwave) infrared spectrum produced by the reradiation of absorbed sunlight.

John Tyndall was the first scientist to study this process in detail by measuring the absorptive properties of air and its key constituent molecules (water vapor and about a dozen different compounds). He used a

sensitive galvanometer to measure the electric current passing through gases irradiated by heat. In 1861, Tyndall concluded that water vapor accounts for most of the atmospheric absorption and hence "every variation of this constituent must produce a change in climate. Similar remarks would apply to the carbonic acid diffused through the air..." (Tyndall, 1861). The next major contribution to the field came just before the end of the 19th century when Svante Arrhenius offered the first calculations of the global surface temperature rise resulting from naturally changing atmospheric CO₂.

Arrhenius's conclusions contained all of the key qualitative modern results. He found that geometric increases of CO₂ will produce a nearly arithmetic rise in surface temperatures, that the warming will be smallest near the equator and highest in polar regions, that the Southern hemisphere will be less affected, and that the warming will reduce temperature differences between night and day (Arrhenius, 1896). His quantitative results also resembled those of today's best global climatic models: he predicted that the increase in average annual temperature will be about 50°C in the tropics and just over 6°C in the Arctic. All of these findings applied to natural fluctuations of atmospheric CO₂: Arrhenius concluded (correctly) that future anthropogenic carbon emissions would be largely absorbed by the ocean and (incorrectly, as he grossly underestimated future fossil fuel combustion) that the accumulation would amount to only about 3 ppm in half a century.

The link between CO₂ and climate change was resurrected in 1938 by George Callendar who calculated a more realistic temperature rise with doubling of CO₂ concentrations (1.5°C rise) and documented a slight global warming trend of 0.25°C for the preceding half a century (Callendar, 1938). In his later writings, he also recognized the importance of carbon emissions from land-use changes. In 1956, Gilbert Plass performed the first computerized calculation of the radiation flux in the main infrared region of CO₂ absorption (Plass, 1956). His results (average surface temperature rise of 3.6°C with the doubled atmospheric CO₂) were published a year before Roger Revelle and Hans Suess summarized the problem with continuing large-scale fossil fuel combustion in such a way that the key sentence has become a citation classic:

Thus human beings are now carrying out a large scale geophysical experiment of a kind that could not have happened in the past nor be reproduced in the future. Within a few centuries we are returning to the atmosphere and oceans the concentrated organic carbon stored in sedimentary rocks over hundreds of millions of years. (Revelle & Suess, 1957)

An almost instant response to this concern was the setting up of the first two permanent stations for

the measurement of background CO₂ concentrations, at Mauna Loa in Hawai'i and at the South Pole. Accumulating measurements began showing a steady rise of atmospheric CO₂ at these two remote locations, but, once again, attention to the problem of potential global warming eased during the 1960s and began to grow only in the aftermath of OPEC's two sudden oil price hikes during the 1970s.

Numerical Models of Anthropogenic Global Warming

By the late 1960s, improvements in computer capabilities made it possible to run the first three-dimensional models of global atmospheric circulation and use them to simulate the effects of higher CO₂ levels. Most of these simulations looked at possible effects arising from the doubling of preindustrial CO₂, that is, after reaching levels around 600 ppm. Initial simulations indicated a 2.93°C rise with the doubling of the CO₂ level to 600 ppm (Manabe & Wetherald, 1967). Increases in computing power (subject to Moore's famous law) and better understanding of interactions between the atmosphere, oceans, and the terrestrial biosphere has led to increasingly more realistic models of global climate. Another important refinement was the inexplicably delayed consideration of other greenhouse gases (above all, of CH₄, N₂O, and chlorofluorocarbons) whose combined radiative forcing is now slightly higher than that of carbon dioxide (about 1.5 and 1.4 W m⁻²).

By the late 1990s, the best models coupled the atmosphere's physical behavior with changes on land and in the ocean, and with simulations of some key features of carbon and sulfur cycles and of atmospheric chemistry (Houghton et al., 2001). At the same time, even our best numerical models still represent the atmosphere with a relatively coarse grid and are incapable of reproducing the intricacies and multiple feedbacks that determine the course and the rate of climate change.

One of the most important sources of potential error in the climate models is the treatment of clouds. The best general circulation models represent fairly well some essential gross features of global atmospheric physics but their iterative calculations are done at such widely spaced points of three-dimensional grids that it is impossible to treat cloudiness in a realistic manner. And yet clouds are key determinants of the planetary radiation balance because they have, on balance, a pronounced net cooling effect. Because clouds account for about half of the Earth's albedo (the fraction of incident radiation that is reflected), even relatively small changes in their properties could have an appreciable effect on the course of global warming.

Other unresolved matters include the response of terrestrial biota (Will carbon sequestration take place

mostly in short- or long-lived tissues or in soil?), marine algae (especially their role in forming clouds), sudden releases of methane (rising temperatures may lead to catastrophic emissions from methane hydrates), and effects of orbital and solar influences (particularly a very high correlation between the solar cycles shorter than the 11-year mean and higher average land temperature of the Northern Hemisphere, and a link between mid-atmospheric temperature and changing intensity of radiation over the sunspot cycle). If the global forecasts are uncertain, regional predictions are particularly questionable. The most complex coupled models now provide reasonably reliable simulations of climate down to the sub-continental level but their results still have unacceptably large variations on regional scales.

Geological Evidence for Global Warming and Cooling

Indirect or proxy markers (such as isotopic and trace chemical analysis on tree rings, ice, or sediment cores) make it clear that a substantial decline of atmospheric CO₂ preceded the most extensive and longest lasting (some 70 million years, or Ma) glaciation of the entire Phanerozoic era that began about 330 Ma ago. Approximate reconstruction of CO₂ levels for the past 300 Ma—since the formation of the Pangea whose eventual break-up led to the current distribution of oceans and land masses—indicates, first, a pronounced rise (about five times the current level during the Triassic period), followed by a steep decline (Berner, 1998; Figure 1, top). Boron-isotope ratios of planktonic foraminifer shells point to CO₂ levels above 2000 ppm 60–50 Ma ago (with peaks above 4000 ppm), followed by an erratic decline to less than 1000 ppm by 40 Ma ago, and relatively stable and low (below 500 ppm) concentrations ever since the early Miocene 24 Ma ago (Pearson & Palmer, 2000; Figure 1, bottom).

Reliable record of atmospheric CO₂ is available only for the past 420,000 years thanks to the analyses of air bubbles from ice cores retrieved from Antarctica and Greenland. Preindustrial CO₂ levels never dipped below 180 ppm and never rose above 300 ppm (Raynaud et al., 1993; Petit et al., 1999; Figure 2) and their oscillations are highly positively correlated with changing temperatures. But these correlations are not a proof of a clear cause-and-effect relationship as there are no obvious lead-lag sequences. Other recent paleoclimatic studies actually found signs of decoupling of atmospheric CO₂ and global climate during the Phanerozoic eon and particularly during the early to middle Miocene, when a warm period coexisted with low CO₂ levels (Veizer et al., 2000; Pagani et al., 1999). These findings confirm the complexity of climate change where cause and effect are difficult to assign: atmospheric CO₂ may have

Figure 1. Atmospheric CO₂ concentrations during the past 300 and 24 million years. Based on Berner (1998) and Pearson and Palmer (2000).

Figure 2. Atmospheric CO₂ concentrations during the past 420,000 years derived from air bubbles in Antarctica's Vostok ice core. Based on Petit et al. (1999).

been a primary climate driver but the evidence is not conclusive (Kump, 2002). The most likely pacemaker during the Pleistocene period was small changes in the Earth's orbit around the Sun; massive methane releases from gas hydrates and volcanic activity must be also considered.

Recent Evidence for Global Warming

During the time between the rise of the first high civilizations (5000–6000 years ago) and the beginning of the fossil fuel era, atmospheric CO₂ levels had fluctuated within an even narrower range of 250–290 ppm. Subsequent anthropogenic emissions pushed atmospheric concentrations of CO₂ to a high of 370 ppm by the year 2000. Paleoclimatic studies of the Northern Hemisphere during the last millennium show

Figure 3. Reconstructed temperature trends during the past 100,000 years (from the Vostok ice core), 1000 years (for the Northern Hemisphere), and a 5-year running mean from instrumental temperature measurements for the past 100 years. Reproduced from Smil (2002).

warming periods during the 12th and 18th centuries and pronounced cooling during the 15th century (the Little Ice Age). A demonstrable cooling trend between the late 18th and the early 20th centuries was followed by an unprecedented rate of warming that has brought the average planetary temperature to levels higher than at any time during the past 1000 years (Figure 3).

The most extensive studies of the existing global record of surface temperatures have detected long-term planetary warming of, respectively, 0.5°C and 0.78°C since the middle of the 19th century (Jones et al., 1986; Hansen & Lebedeff, 1988). Changes in measurement techniques (different thermometers), station locations (from downtowns to suburbs) and station environment (increasing urban heat island effect), and until very recently, highly inadequate coverage of large areas of the Southern Hemisphere complicate the interpretation of this shift, which has distinct spatial patterns with areas of more pronounced warming and regions of slight cooling. However, the most recent (post-1976) spell of warming has been almost global and the 1990s were the warmest decade since the beginning of the

Figure 4. Estimates of cumulative radiation forcings by greenhouse gases and aerosols between 1850 and 2000 according to Hansen et al. (2000).

instrumental record in the 1850s and the warmest ten years of the millennium in the Northern Hemisphere.

According to the general circulation models, the warming should have been more pronounced. The best explanation of the discrepancy between the models and the actual temperature record is that the warming was partially counteracted by sulfate aerosols. The combined direct and indirect effect of all greenhouse gases resulted in a total anthropogenic forcing of about 2.8 W m^{-2} by the late 1990s (Hansen et al., 2000; Figure 4). This is equal to a little more than 1% of solar radiation reaching the ground.

Future Climate

If the atmospheric warming was primarily the function of radiative forcing, then the level of greenhouse gas emissions would be the key variable. Recent emission scenarios for CO₂ alone offer a very large range of concentrations, 540–970 ppm, by the year 2100. CH₄ levels may range even wider, from just above 1500 ppb to more than 3600 ppb. The aggregate radiative forcing may thus be anywhere between 4 and 9 W m^{-2} and the climate sensitivity would then range between 1.5°C and 4°C with 2.2 – 3°C considered to be the most likely by the latest IPCC assessment. Broad consensus from the latest generation of models foresees that this climatic change would cool the stratosphere while raising the tropospheric temperatures in a distinct spatial pattern, with the warming more pronounced on the land (and during nights) and with increases of about two to three times the global mean in higher latitudes in winter than in the tropics, and greater in the Arctic than in the Antarctic.

There are many effective ways to slow down the greenhouse gas emissions and reduce their environmental impact. Most significantly, the affluent countries could largely retain their quality of life while reducing their energy and material consumption by at least a third. While the means are available, the will to act, nationally and internationally, is mostly absent. Global warming is a complex natural process but its

anthropogenic enhancement calls for a fundamentally moral solution that runs against some basic human propensities: consume less and do so more efficiently.

GRADIENT SYSTEM

In the study of dynamic systems, it is often observed that the rate of evolution of some system in its phase space is proportional to the gradient of a state function. A system of this type is called a *gradient system*, and the state function—which governs the course of its evolution—is its *potential*.

If the state s of a system is given by n state variables $s_1, \dots, s_n$ and $G(s) = G(s_1, \dots, s_n)$ is the potential of the system, then one can write (in matrix form)

$$\dot{s} = -\hat{k} \cdot \left(\frac{\partial G}{\partial s} \right)^T. \quad (1)$$

Here the rate of change of state s is given by the column vector $\dot{s} = |\dot{s}_1, \dots, \dot{s}_n|^T$, where the superscript T indicates transposition; $\partial G(s)/\partial s = |\partial G/\partial s_1, \dots, \partial G/\partial s_n|$ is the row vector of gradient of potential $G(s)$; and $\hat{k}$ is a coefficient of proportionality, represented by the nonsingular matrix $\hat{k} = |k_{ij}|$, $\det |k_{ij}| \neq 0$. The minus sign in Equation (1) is chosen for convenience. The coordinate representation of this equation is

$$\dot{s}_i = - \sum_{j=1}^n k_{ij} \frac{\partial G}{\partial s_j} \quad (i = 1, \dots, n). \quad (2)$$

Equations (1) and (2) are quite general. For example, if the order n is an even number ($n = 2m$, $m \geq 1$), and $\hat{k}$ is a $2m \times 2m$ block-diagonal matrix composed of the skew-symmetric blocks,

$$\begin{aligned} \hat{k} &= \text{diag}[\hat{k}_1, \dots, \hat{k}_m], \quad \hat{k}_1 = \hat{k}_2 = \dots = \hat{k}_m \\ &= \begin{pmatrix} 0 & -1 \\ 1 & 0 \end{pmatrix}, \end{aligned} \quad (3)$$

then Equations (1) and (2) are the usual Hamiltonian system (Fomenko, 1995).

However, gradient systems differ radically from Hamiltonian systems. Essential restrictions that specialize the definition of gradient systems and predetermine their qualitative properties are on the structure of matrix $\hat{k}$. For a gradient system: (i) The nonsingular matrix $\hat{k}$ is assumed to be symmetric: ($\hat{k} = \hat{k}^T$ or $k_{ij} = k_{ji}$); hence, it possesses exactly n nonzero eigenvalues that the real numbers. (ii) All eigenvalues of $\hat{k}$ are assumed to have the same signs, either positive or negative.

Note that requiring that the rates $\dot{s}$ be proportional to the gradient of potential $G(s)$ does not oblige the coefficient of proportionality $\hat{k}$ to be a constant matrix. In general, the elements of $\hat{k}$ can (smoothly) depend on the current state s : $k_{ij} = k_{ji}(s)$, suggesting a third requirement of a gradient system: (iii) The properties (i) and (ii) must be fulfilled everywhere in the state space of system. Thus, a gradient system is defined as a system, whose evolution follows Equations (1) and (2), with a matrix satisfying conditions (i)–(iii).

The key dynamic difference between Hamiltonian and gradient systems is that Hamiltonian systems preserve the values of system potential, the Hamiltonian function ($\dot{G}(s) = 0$). The behavior of a gradient system is quite different because the matrix $\hat{k}$ in (3) is symmetric rather than skew-symmetric; thus $\dot{G}(s) \neq 0$.

From conditions (i)–(iii), one can demonstrate that the evolution of a gradient system preserves the sign of $\dot{G}(s)$; hence, the potential $G(s)$ either decreases or increases monotonically. To see this, consider the dissipative function of a gradient system, which is introduced by the quadratic form

$$\Gamma = \frac{1}{2} \dot{s}^T \hat{\gamma} \dot{s} = \frac{1}{2} \sum_{i,j=1}^n \gamma_{ij} \dot{s}_i \dot{s}_j \quad \text{where} \quad \hat{\gamma} = \hat{k}^{-1}. \quad (4)$$

The matrix $\hat{\gamma}$ inherits the properties (i)–(iii) of matrix $\hat{k}$, and the constancy of sign $\dot{G}(s)$ under the evolution of a gradient system follows directly from the relation

$$\dot{G}(s) = -2\Gamma. \quad (5)$$

Relation (5) indicates that the sign of $\dot{G}(s)$ is opposite to the sign of dissipative function; thus, as the latter is

positively (negatively) definite, the potential of gradient system strictly decreases (increases).

As an elementary example, the ordinary equation $\dot{u} = f(u)$ is a gradient system because it admits the representation $\dot{u} = -k[dG(u)/du]$, $k = 1$, $G(u) = -\int f(u)du$. The corresponding dissipative function is $\Gamma = \dot{u}^2/2$, and under time-dependent solutions of this equation, the potential decreases monotonically.

As a second example, consider a Newtonian particle of mass m that is changing its position $\mathbf{r}$ with the speed $\dot{\mathbf{r}}$ and acceleration $\ddot{\mathbf{r}}$ by the action of forces of two kinds: a potential force $\mathbf{Q}^{(P)} = -\text{grad}G(\mathbf{r})$ (where $G(\mathbf{r})$ is the potential energy), and a friction force $\mathbf{Q}^{(D)} = -\gamma\dot{\mathbf{r}}$, $\gamma = \text{const} > 0$. The Newtonian vector equation of motion of this particle is $m\ddot{\mathbf{r}} = \mathbf{Q}^{(D)} + \mathbf{Q}^{(P)} \equiv -\gamma\dot{\mathbf{r}} - \text{grad}G(\mathbf{r})$, or, equivalently,

$$\dot{\mathbf{r}} = \mathbf{v}, \quad m\dot{\mathbf{v}} + \gamma\mathbf{v} = -\text{grad}G(\mathbf{r}). \quad (6)$$

This system has two different limits—"Galilean" and "Aristotelian." The Galilean limit corresponds to the situation when dissipative force $\mathbf{Q}^{(D)}$ is negligible in comparison with the d'Alembert inertia force $\mathbf{Q}^{(I)} = -m\dot{\mathbf{v}}$. At this limit—which is realized under motion through a vacuum—the term $\gamma\mathbf{v}$ in Equations (6) vanishes, and it reduces to the form

$$\dot{\mathbf{r}} = \mathbf{v}, \quad m\dot{\mathbf{v}} = -\text{grad}G(\mathbf{r}). \quad (7)$$

We refer to this limit as Galilean because Galileo proposed and experimentally demonstrated that gravitational force determines the acceleration of a falling body rather than its speed.

The Aristotelian limit, on the other hand, describes so-called creeping motions, in which the d'Alembert inertia force $\mathbf{Q}^{(I)}$ is much weaker than the dissipative force $\mathbf{Q}^{(D)}$: $|\mathbf{Q}^{(D)}| = m|\dot{\mathbf{v}}| \ll |\mathbf{Q}^{(I)}| = \gamma|\mathbf{v}|$. This limit is realized in the viscosity limited motion of particle, which occurs in a strongly viscous medium in the presence of a potential force field. In this limit, Equations (6) asymptotically reduce to

$$\dot{\mathbf{r}} = -k\text{grad}G(\mathbf{r}), \quad k = \gamma^{-1}. \quad (8)$$

The order of Equation (8) with respect to time is less by half than corresponding order of (6). In this case, the current state s of particle is fully determined by current value of radius-vector $\mathbf{r}$. Now, the rate of change of state is proportional to the gradient of potential energy; therefore, the Newtonian particle undergoes creeping motion in a gradient system. The dissipative function of this system is

$$\Gamma = \gamma\mathbf{v}^2/2 \quad (\gamma > 0), \quad (9)$$

and the potential $G(\mathbf{r})$ always decreases monotonically as $\dot{G} = -\gamma|\text{grad}G(\mathbf{r})|^2$. This limit is called Aristotelian because it manifests the Aristotelian principle that "velocity of a body is proportional to a force acting upon the body." (This principle is not wrong; it merely corresponds to one of two possible limits of classical macroscopic dynamics which is realized in the presence of strong friction.)

The Newtonian example can be extended to the more general case of constrained system of n degrees of freedom, which move under stationary holonomic constraints and generalized forces of three types: the potential forces $Q_i^{(P)}$, the dissipative forces $Q_i^{(D)}$ of viscous friction, and the d'Alembert inertia forces ($Q_i^{(I)} = 1, \dots, n$). A related example is provided by electrical networks that are constructed with linear lumped elements: resistances (R), inductances (L), and capacitances (C). From an electromechanical analogy (Gantmacher, 1975), the considerations discussed above are extended to this case almost automatically. The analogs of Galilean and Aristotelian limits also exist here. The first limit corresponds to the situation when all resistances are negligible; it displays the LC subclass of general RLC networks. The networks belonging to this subclass are described by systems of ordinary differential equations that involve second-order time derivatives; as a rule, they are not gradient systems. The electrical analog of the Aristotelian limit corresponds to the networks with negligible inductances (RC subclass of general RLC networks). The networks making up this subclass are gradient systems.

The gradient systems considered in these examples are characterized by the monotonic diminution of potential G in their motions. Formally, this property follows from positiveness of dissipative functions related to these systems. In the mechanical examples, where the potential G is given by the potential energy of a mechanical system, its diminution can be explained physically by the action of viscous friction, which dissipates the energy of system and fully converts it to heat Q at a rate $dQ/dt = 2\Gamma$.

The opposite case, which corresponds to a monotonic increase of G , can be viewed as the action of "negative friction" transferring energy from exterior sources to the moving system; for example, processes during evolution of the genetic structure of biological populations which are described by classical Fisher-Haldane-Wright equations. The gradient representations of these equations were developed by Svirezhev in 1972 and by Shahshahani in 1979. (Svirezhev's results now can be found in the comprehensive monograph of Svirezhev & Pasekov, 1990.) In the context of their results, the famous Fisher's Fundamental Theorem of Natural Selection—which asserts that the mean fitness of population always increases with the rate proportional to the genotypical diversity of the population—is

a simple consequence of the gradient properties of the equations. In this case, the role of potential of the corresponding gradient system is played by the mean fitness of population, whereas the dissipative function is connected with a certain measure of genotypical diversity.

Owing to the presence of the monotonically varying quantity G , any gradient system is forbidden to return to states it once already left. In particular, such a system cannot perform nontrivial periodic motions (different from the states of rest). These properties are widely used in applied mathematics, including numerical gradient methods of searching for minima and maxima of multivariable functions.

In the above examples, gradient systems with finite degrees of freedom were considered. However, in various problems one deals with nonlocal spatially distributed systems in continuous media, occupying some d -dimensional region X of physical space, whose dynamics inherits the main features of finite-dimensional gradient systems. These objects form a class of gradient systems of an infinite number of degrees of freedom, which are referred to as *continuum gradient systems*. A nontrivial example is the system

$$\dot{u} = -k(u, \mathbf{x}) \frac{\delta G[u]}{\delta u},$$

$$G[u] = \int_X g(u, \nabla u, \mathbf{x}) dX, \quad (10)$$

where $u = u(\mathbf{x}, t)$ is a function describing the state of the system at the spatial point $\mathbf{x} \equiv (x_1, \dots, x_d) \in X$ and time t , and the integral functional $G[u]$ is a potential of the continual gradient system. Also ∇u denotes the spatial gradient, $\nabla u = |\partial u / \partial x_1, \dots, \partial u / \partial x_d|$; $dX = dx^1 \dots dx^d$ is the space volume element of the region X occupied by the continuous medium; and $\delta / \delta u$ is a functional derivative, which acts upon the functional $G[u]$ according to the rule

$$\frac{\delta G}{\delta u} = \frac{\partial g}{\partial u} - \operatorname{div} \left[\frac{\partial g}{\partial (\nabla u)} \right]$$

$$= \frac{\partial g}{\partial u} - \sum_{\mu=1}^d \frac{\partial}{\partial x^\mu} \frac{\partial g}{\partial (\partial u / \partial x^\mu)}. \quad (11)$$

Substituting (11) into the second part of (10), one can show that equations (10) are equivalent to the equation

$$\dot{u} + \operatorname{div} \mathbf{J} = Q \quad (12)$$

where $\mathbf{J}$ and Q are given by the expressions

$$\mathbf{J} = -k \frac{\partial g}{\partial (\nabla u)}, \quad (13)$$

$$Q = -k \frac{\partial g}{\partial u} - \nabla k \cdot \frac{\partial g}{\partial (\nabla u)}. \quad (14)$$

Equation (12) has the form of standard continuity equations for some substance filling the spatial region X ; therefore, the quantities u and $\mathbf{J}$ can be interpreted as the density of this substance and as a vector of density of the corresponding spatial transport flux, respectively. From this standpoint, the function in the second part of continuity equation (12), defined by relationship (14), describes the rate of production of these substances per unit space volume, whereas expression (13) relating the flux $\mathbf{J}$ to the density u and its spatial gradient ∇u can be interpreted as a peculiar nonlinear generalization of well-known linear phenomenological laws such as Fick's law of diffusion or Ohm's law of electrical conduction. Hence, the continuum physical systems obeying the functional gradient equation (10) constitute a specific subclass in the class of reaction diffusion systems. This subclass comprises many physically important systems, including the parabolic equation

$$\gamma(\mathbf{x}) \dot{u} = \operatorname{div}[D(\mathbf{x}) \nabla u] + f(u, \mathbf{x})$$

$$= D(\mathbf{x}) \Delta u + \nabla D(\mathbf{x}) \cdot \nabla u + f(u, \mathbf{x}) \quad (15)$$

defined in the space region X . Here $\gamma(\mathbf{x}) > 0$, $D(\mathbf{x}) > 0$, and $f(u, \mathbf{x})$ are the given functions of their arguments. Special cases of (15) include the linear diffusion equation $\dot{u} = \Delta u$, as well as the nonlinear reaction diffusion equation

$$\dot{u} = \Delta u + f(u), \quad (16)$$

which arises in several branches of natural science.

In mathematical genetics, Equation (16) describes the gene exchange waves traveling in the populations of biological organisms (Fisher's equation). In addition, this equation describes flame propagation as well as the switching processes in some physical, chemical, and biological nonlinear media (Zeldovich–Frank–Kamenetsky equation). Also, the time-dependent Ginzburg–Landau equation, which arises in physical kinetics and in synergetics for the phase transitions in spatially distributed self-organizing systems, has the form of Equation (16).

Remarkably, all these examples can be interpreted as processes of time evolution of certain gradient continuum systems. The functional gradient representation (10) is important because it suggests their general qualitative properties by the analogy with finite-dimensional case. For example, the potential $G[u]$ in (10) decreases monotonously in all time-dependent solutions if the latter is endowed with impermeability boundary conditions [see (18)]

$$J_n|_{\partial X} = 0 \leftrightarrow \mathbf{n} \cdot \frac{\partial g}{\partial (\nabla u)} \Big|_{\partial X} = 0, \quad (17)$$

where the subscript ∂X indicates that corresponding expressions are considered at the boundary ∂X of space region X enclosing the continual system, $J_n|_{\partial X}$ is the normal component of $\mathbf{J}$ at the boundary, and $\mathbf{n}$ is unit normal vector at ∂X . Indeed, the full derivative of the energy functional $G[u]$ with respect to time t is given by the elegant relation

$$\frac{dG}{dt} = - \int_X k \left(\frac{\delta G}{\delta u} \right)^2 dX \leq 0. \quad (18)$$

Defining the *dissipative functional* by the formula

$$\Gamma[u, \dot{u}] = \int_X \frac{1}{2k} \dot{u}^2 dX = \frac{1}{2} \int_X \gamma \dot{u}^2 dX, \\ \gamma = k^{-1},$$

puts (18) into the simple form of Equation (5), which appeared in the finite-dimensional case.

As in the finite-dimensional case, the monotone decrease of potential means that time evolution is *unidirectional*—these systems cannot return to the states once left. In particular, they can have neither solutions that are periodic in space and time nor traveling-impulse solutions with complete recovery of the initial state. If they possess moving wave-front solutions, contra directional wave fronts cannot be reflected after collisions with each other. On the contrary, if some spatially distributed system isolated from the outer world by the impermeable boundaries can modify its state supporting the propagation of solitary/periodic traveling pulses, then it cannot be described by continuum gradient equations.

GRANULAR MATERIALS

What do coffee powder, wheat, mustard seeds, granulated sugar, cement, sand, and rocks have in common? They are granular materials, assemblies of solid objects, from tens of micrometers to meter sized, that are generally not bound together by significant attractive forces. Such assemblies of objects possess unique physical and dynamic characteristics. Even though individual grains are solid particles, the assembly of grains behaves distinctly from ordinary solids, fluids, or gases (Jeager et al., 1996; Duran, 1997). For example, a sand dune is reliably solid-like and can sustain the weight of a person. However, if the sand from the dune is placed in an hourglass, it will flow rapidly and at a predictable rate.

The curious behavior of granular matter has long attracted the attention of scientists. In 1885, Osborne Reynolds observed that in order for grains to flow past each other, they have to move out of each other's way, leading to a dilation of granular matter under shear (Reynolds, 1885).

Some of the first modern work on granular matter was inspired by Per Bak, C. Tang, and K. Wiesenfeld (1987), who developed the concept that many systems may self-organize into a critical state. Granular avalanching was thought to be one of the prominent experimental realizations of their theory of self-organized criticality (SOC). The idea was that on a sandpile, grains might self-organize through avalanching to form a heap with a critical angle, which is called the angle of repose of the sandpile.

While experiments showed that SOC does not describe the behavior of real sandpiles (Nagel, 1992), the initial experiments showed some of the puzzling properties of granular matter and inspired a significant resurgence of research into granular matter. Here we describe three of the main questions of recent work:

When and How Does Granular Matter Flow?

In most situations when granular matter flows, such as during emptying of silos or during natural rock avalanches, only part of the material behaves like a fluid. This is illustrated in Figure 1 in a long exposure image of the side of an avalanche flowing down the

Figure 1. Long exposure image of the side of an avalanche flowing down the side of a granular pile. A clear separation into fluid-like and solid-like regions is visible. (Courtesy of N. Taberlet and P. Richard, University of Rennes).

side of a granular pile. The flow leaves behind a pile with a known surface angle, the angle of repose (Nagel, 1992). Predicting the timing and extent of such partial fluidization is part of the current challenge of modeling dense granular flows.

Once flowing, hydrodynamic equations may describe the flow behavior (Losert et al., 2000), though velocity gradients on length scales of a few particle diameters can call the validity of continuum models with local equilibria into question.

More dilute flows can be modeled as a system of hard spheres in which some energy is lost during each collision. Based on such a picture, kinetic theories of driven granular media have been developed, for example by Goldhirsch & Zanetti (1993). Since energy is continuously lost in collisions and must be added through gravity or shaking, granular flows are non-equilibrium driven, dissipative systems that exhibit interesting instabilities. One example is the clustering instability, in which a dilute system of particles can spontaneously develop localized, dense clusters (Goldhirsch & Zanetti, 1993). The basic mechanism for and clustering is that a local increase in particle density increases the number of collisions in that region, and, thus, slowing particles down and trapping them in the dense region.

How Can Different Kinds of Particles be Mixed or Separated?

During flow, mixtures of grains tend to spontaneously unmix (Shinbrot & Muzzio, 2000), as illustrated in Figure 2. The figure shows unmixing in a mixture of glass particles of three different sizes after several rotations in a half-filled horizontal cylinder. The phenomenology of granular unmixing is complex. In a horizontally rotating drum, for example, materials can segregate both radially and axially by size or by density. There is, to date, no simple model for unmixing, but a wealth of empirical experimental data and several simple physical mechanisms, such as

Figure 2. Unmixing of grains of three different sizes in a rotating horizontal cylinder. After 5 min of rotation at 15 rpm, material is separated into axial and radial bands. Both a side view and end view of the cylinder are shown.

Figure 3. Forces in a 2-dimensional assembly of disks sheared between concentric cylinders. The disks are birefringent and placed between crossed polarizers, so that only points subject to large forces are visible as bright regions. (Courtesy of B. Utter and R.P. Behringer, Duke University).

percolation through voids, shear flows, and convection, all play some role in the unmixing process.

How Are Forces Transmitted Through Granular Matter?

In civil engineering, the mechanical behavior of granular matter is modeled by solid-like equations (Nedderman, 1992). Zooming in to the scale of grains, forces can only be transmitted at particle contacts, and only repulsive forces are permitted at each contact. This can lead to very inhomogeneous force distributions and locally very large forces as is indeed seen, for example, in grain silos. Experiments with birefringent disks that highlight the location and magnitude of contact forces (Howell et al., 1999) have helped in our microscopic understanding of the way forces are transmitted through granular matter (Figure 3). Strong inhomogeneities in the force magnitude, anisotropies in the direction of stress

transmission, and large rearrangements in the force distribution, even for small changes in structure are observed.

Two emerging concepts to explain the properties of such dense granular matter are jamming, the property of a system to get trapped in some intermediate state which may be generic to granular matter as well as thermal systems such as glasses, and the idea of stress chains, lines of particles that carry disproportionately large stress, as can be seen in Figure 3.

To conclude, basic questions about granular matter remain. Granular matter encompasses different kinds of particles with many variables, such as the frictional properties of grain-grain or grain-boundary contacts, the deformability, surface roughness, polydispersity, and grain shape. It remains difficult to predict whether a particular granular parameter, such as the shape of individual grains will qualitatively alter flow, forces, or mixing behavior, and thus, has to be taken into account in modeling. While models for flow, forces, and segregation have been developed that agree with experimental data under various conditions, a broadly valid model of granular flow based on simple physical insights similar to the Navier–Stokes equation for fluids has so far proven elusive. Similarly, no consensus about the most suitable equation for granular solids has yet emerged, nor has a clear separation between the solid-like and liquid-like regime emerged.

GRAVITATIONAL WAVES

In 1687, Newton published *The Philosophiæ Naturalis Principia Mathematica* in which he first proposed his law of gravitation. According to this law, the gravitational force of attraction between two bodies is always proportional to their masses and inversely proportional to the square of their distance apart, and it acts instantaneously through infinite distance. Less than two and half centuries later, Newton's theory was radically revised.

According to Einstein's general theory of relativity (published in 1913), gravitation is not a force of attraction but rather the force required to prevent the natural motion of matter, which is to follow a geodesic in space time. The geodesic or shortest path in four-dimensional space time describes a free-fall trajectory such as the motion of a planet around the sun. The space time is curved by the presence of matter or energy. The predictions of general relativity are very close to those of Newtonian theory as long as gravity is weak and velocities are slow, but they diverge in strong gravity due to two aspects of the theory. The first is the change in geometry due to the non-Euclidean properties of space time. The second stems from the nonlinear aspects of general relativity, which arise because gravitational energy is itself a source of curvature.

Eight years prior to publishing his general relativity theory, Einstein published the special theory of relativity, which predicted that neither matter nor information could ever travel faster than the speed of light. This means that the curvature at a point generated by a mass at another point only achieves its value at a retarded time, a time set by the travel time for light between the two points.

The general theory of relativity changed our vision of a Euclidean flat space that had been assumed since the days of Newton. In non-Euclidean space, the sum of the angles of a triangle does not equal 180° and the area of a circle is not always πr^2 . Space time can be considered as an elastic membrane. The deformations are described by the Einstein curvature tensor G , while the sources of curvature (i.e., the mass-energy distribution) are described by the stress-energy tensor T . Einstein's field equations are then expressed by the equation (Misner et al., 1973)

$$T = \frac{c^4}{8\pi G} G. \quad (1)$$

The constant $c^4/8\pi G$ (where c is the speed of light and G is Newton's gravitational constant) is a very large number which can be considered as the "spring constant" of space time. Because it is so large, only very small curvatures are generated even by very large values of mass-energy distribution. A natural consequence of the membrane analogy is the existence

of waves; ripples in the curvature of the membrane which propagate through the membrane. This concept can also be deduced from Einstein's field equations.

Equation (1) is a set of ten nonlinear equations. Except in simplified situations, these equations are difficult to solve directly. Matter creates curvature and curvature influences the motion of matter. This mutual influence gives rise to nonlinear phenomena in gravitational wave propagation. Unlike the theory of electromagnetism, the theory of general relativity is intrinsically nonlinear. Since gravity is itself a source of curvature, there can be a gravitational interaction between gravitational waves. While gravitational wave signals are normally expected to be very small (and hence amenable to a linearized theory), at their sources, the nonlinear aspect of the theory makes prediction extremely difficult. The following list offers some examples of expected nonlinear phenomena in gravitational wave propagation:

- For gravitational waves emerging from the birth of a black hole, the gravitational redshift of the waves reduces the total emitted energy. The mass-energy of the gravitational waves themselves constitute the redshift.
- Like electromagnetic radiation, gravitational waves can undergo gravitational lensing. A mass in the path of the waves creates a background curvature. This curvature focuses the waves by modifying the wave front. This effect can enhance the intensity of dim sources. The gravitational lensing effect has successfully been observed for electromagnetic radiation.
- A time-varying curvature can amplify waves. If a wave modulates the space curvature, a second incident wave will be amplified or its frequency shifted. An optical parametric oscillator represents the equivalent phenomena for optical radiation. Similar to the optical Kerr effect, a gravitational wave can interact with its own self-generated background curvature. In the early universe, it is predicted that gravitational waves from the Big Bang may have been parametrically amplified by the action of inflation.
- A strong background curvature (e.g., from a black hole) can scatter a gravitational wave passing in its vicinity.

Under gravitational wave astronomy, it may be possible to find evidence of these predicted phenomena. The first indirect experimental proof of gravitational waves was provided in 1984 by Weisberg and Taylor. By studying the pulsar PSR 1913+16, they showed that the period of the pulsar around its companion star decreased exactly as predicted by the Einstein equations (Weisberg et al., 1981). A part of the pulsar orbital energy is converted to gravitational radiation.

The orbital parameters of binary stars are usually deduced from measurements of the Doppler shift of the radiated electromagnetic waves. According to Newtonian gravitational theory, the mass m_1 of the pulsar and the mass m_2 of its companion cannot be determined with confidence. All results obtained are proportional to an unknown parameter: the sine (normally denoted $\sin i$) of the angle between the orbital plane and the line of sight. This parameter can be evaluated in the framework of general relativity. From this theory, five independent parameters (among them, the advance of the periastron (the point of closest approach of the two stars), the evolution of the period, or the Einstein parameter) which are functions of m_1, m_2 , and $\sin i$ can be measured. The overdetermined system of five equations determines with an unprecedented accuracy (error less than 0.5%) the mass of the pulsar. Moreover, the compatible results from the five independent equations confirm the general theory of relativity in the strong field and radiative regime. This high-precision validation of general relativity indirectly implies that the velocity of gravitational waves is equal to the speed of light.

Direct detection of gravitational waves on Earth is one of the most exciting challenges of today's science. In the 1960s, Joseph Weber invented and developed the first gravitational wave detectors, consisting of large (about a ton) vibration-isolated cylinders of aluminum or niobium (Weber, 1960). The gravitational waves excite the longitudinal resonance in the cylinder, which behaves as an extremely low-loss mechanical oscillator. The motion of the cylinder is monitored to very high precision. Most of its motion is thermal vibration but the small effect of the gravitational waves appear as very small perturbations in the amplitude or phase of the vibration. The mechanical oscillations, converted into an electrical signal, are recorded and analyzed by sophisticated predictive filter algorithms. A worldwide network of five resonant bars still uses Weber's technique (see Figure 1).

A new generation of gravity-wave detectors is based on laser interferometry (Blair, 1991). Gravitational waves passing through a Michelson interferometer change the relative length difference between the two perpendicular arms of the interferometer. Thus the variation of the gravitational field can be converted to an optical phase variation. Due to the weakness of gravitational wave interaction with matter, the detectors must be able to measure a length variation of less than 10^{-18} m, which is close to the quantum limit. Compared with the resonant bar, the interferometric devices exhibit a larger bandwidth and higher sensitivity. The sensitivity is limited by seismic and thermal noise at low frequency and photon-counting noise at higher frequency.

Five international projects, similar to the example shown in Figure 2, are using long base interferometry

Figure 1. Photograph of the interior of Niobe, the resonant bar at the University of Western Australia. The bar is a one and half ton cylinder of niobium cooled to 5 K to limit the thermal noise.

Figure 2. Aerial view of the French–Italian gravitational waves detector VIRGO near Pisa in Italy. On this photo, the two perpendicular 3 km vacuum pipes containing the arms of the interferometer are clearly distinct (Bradaschia et al., 1990) (Reproduced with permission from EGO).

to detect gravitational waves. The network of, interferometers (situated in the United States, Europe, Japan, and Australia) will enable the localization of sources of gravitational radiation in space as well as determination of their polarization. By measuring the arrival time of the waves at different detectors, the speed of the gravity waves can be calculated. This speed could be influenced by two independent factors: a coupling of the wave with a strong curvature background (difficult to detect on Earth) and the possibility that the graviton, the particle associated with the gravitational waves, is not massless (Will, 1998).
